Although the discussion about the safety (or the lack thereof) of launching a Centaur liquid oxygen/liquid hydrogen upper stage as payload from the payload bay of the Space Shuttle has been going on for a long time, only to be eventually canceled, an even more daring launch sequence would have been to fly a fluorine oxidizer upper stage or spacecraft as payload in the Space Shuttle payload bay. The safety and hazards of this project have been thoroughly reviewed, only to suffer the same fate as the Shuttle/Centaur project, being canceled for the sake of safety. The safety implications of Space Shuttle-launched spacecraft using liquid fluorine as the oxidizer for upper stage or spacecraft propulsion were thoroughly investigated. It would be important to always have sufficient liquid nitrogen available to keep the fluorine cold while it is flown to its point of use [347–349]. The feasibility of safe operation was examined and all equipment and procedures necessary to maximize the chance of success were determined. Hazards to the shuttle were found to be similar in kind if not degree to those encountered in the use of dinitrogen tetroxide (also a toxic oxidizer). It was concluded that residual risks from spacecraft using fluorine and nitrogen tetroxide during ground and flight handling can be reduced by isolation of the oxidizer to only its tank. Operation of planetary spacecraft propulsion in the vicinity of the shuttle in earth orbit is not required. The primary hazard to personnel was identified as propellant-loading operations on the ground, which should be accomplished in an area reasonably remote from uninvolved personnel and facilities concentrations. Clearing the pad from all personnel during spacecraft mating with the shuttle orbiter was recommended.

4.2.1 Metals Compatibility with Flowing Liquid Fluorine

Although most compatibility tests were conducted with stagnant propellants, a few were conducted under aggravated conditions with flowing fluorine. The effect of liquid fluorine on metals differs significantly depending on the conditions of exposure, if the metal is exposed to stagnant or flowing fluorine. In a test with liquid fluorine, several candidate metals (nickel, stainless steel, aluminum, brass) were formed into three different test body shapes (capillary tube, a flat bolt, and a triangular sharp-edged wedge behind which turbulent eddies would form) and exposed to flowing liquid fluorine at up to $10.1 \text{ MPa} = 100 \text{ atm} = 1470 \text{ psia}$ and flow velocities up to 120 m/s [350]. All four materials tested were suitable for exposure to liquid fluorine under these conditions, which resembled those in a propellant feed system at a rocket test site [351].

The dynamic compatibility of liquid and gaseous fluorine with metals was examined by exposing 11 metallic materials of construction (301 cryoformed, 304L, 321, and 347 stainless steel; A-286 super alloy steel; 2219, and 6061 aluminum; oxygen-free high thermal conductivity (OFHC) copper; Monel K-500; Inconel 718; and Nickel 200) to flowing fluorine [352]. Six types of tests were used to obtain the data required to establish safe design criteria for fluorine systems: (1) maximum velocity, (2) adiabatic compression (U-tube), (3) liquid impact, (4) flexing/film degradation, (5) vibration/film degradation, (6) liquid phase shock wave. Flow tests with gaseous, preheated

fluorine on heated specimens were conducted with nine metals. The fluorine gas pressure upstream of the test specimen was nominally 689 kPa (100 psia) throughout the investigation. From this type of analysis alone, the threshold temperatures for incipient failure could be defined by the onset of large exotherms. The mechanism of failure was, however, evident only by examination of the “failed” specimen. A “failed” specimen of 304-L stainless steel showed that the ultimate failure was brought about by burning. From all the data available, it was concluded that nickel is the best metal known for containing hot, flowing, gaseous fluorine. In descending order of preference, the other metals studied were ranked as follows: Inconel 718 and Monel K-500 > austenitic stainless steels > copper > aluminum. The results of adiabatic compression tests are summarized in Table 39. Similar tests were conducted for chlorine pentafluoride in parallel with the fluorine tests. The report also contained a very good summary of metals reactivity test results reported by other organizations.

Table 39: Terminal adiabatic compression conditions that result in a 50% probability of fluorine/metal reaction.

Metal	Calculated final temperature		Calculated final density		Extent of resulting reaction
	K	°F	g/cm ³	lb/ft ³	
6061-T6 Aluminum	~994*	~1330 ^a	~0.096	~5.97	Major
A-286 Stainless Steel	978	1300	0.089	5.57	Variable
304-L Stainless Steel	983	1310	0.090	5.64	Slight
304-L Stainless Steel	1089	1500	0.047	2.96	Slight
321 Stainless Steel	1075	1475	0.046	2.9	Variable
347 Stainless Steel	~1191 ^a	~1685 ^a	~0.067 ^a	~4.16 ^a	Major
Inconel 718	~1191 ^a	~1685 ^a	~0.067 ^a	~4.16 ^a	Slight
Monel K-500	~980	~1305	~0.089	~5.55	Variable
Monel K-500	~1164	~1635	~0.061	~3.82	Slight
OFHC Copper	Not Defined				Insignificant
Nickel 200	Not Defined				Insignificant

^a Insufficient positive reaction data points to define reaction probability accurately
Data source: [352]

From the data presented in Table 39, it was concluded that the metals can be ranked in categories in the following descending order of resistance to the effects of fluorine adiabatic compression: (1) Nickel 200 and OFHC copper, (2) Inconel 718, and (3) 304-L, 321 and A-286 stainless steels. The proper ranking of Monel K-500, 6061-T6 aluminum, and 347 stainless steel was uncertain because of insufficient or irregular positive test results.

4.2.2 Copper in Contact with Liquid Fluorine

Pure copper and soft copper alloys have been used for crush gaskets.

4.2.3 Stainless Steel in Contact with Liquid Fluorine

Stainless steels of the 300 series, nickel, Monel, and K-Monel are suitable materials of construction for pumps and propellant feed systems [353]. Bell Aircraft designed a test stand for rocket engine firings with liquid fluorine and FLOX. Between 1956 and 1960, more than 50000 lb of liquid fluorine had been processed at that facility without any accidents. More than 500 test firings with thrust chambers with small and intermediate thrust were performed. The fluorine flow rates were up to 70 lb/s with linear flow velocities of >100 ft/s and feed pressures of 500 psi. On-site stationary storage of LF2 was in a triple-walled storage vessel. The innermost container from 300-series stainless steel held the LF2 and the intermediate surrounding tank contained LN2. All valves had long stem extensions to maintain a safe distance between valve and operator, separated by metal shields. Liquid level gauges could not be incorporated into the tank in order to keep the tank wall penetrations to a minimum, only for a gas inlet and a standpipe outlet.

4.2.4 Titanium in Contact with Liquid Fluorine

Unalloyed titanium and four titanium–base alloys were subjected to a simple preliminary corrosion evaluation in liquid and gaseous fluorine at temperatures between 77 and 378 K (–320 and +220 °F) [291]. All materials exhibited tolerable corrosion resistance under the test conditions. More elaborate experiments would be required to fully establish the utility and safety of titanium in fluorine service.

The compatibility of Ti-6Al-4V with propellant-grade gaseous fluorine and liquid fluorine at 77 K was investigated for up to 3 years [354]. The specimens of Ti-6Al-4V in two heat-treat conditions (annealed, 147 KSI, and heat-treated, 175 KSI) and two surface finishes (16 and 64 RMS) were immersed in liquid fluorine in individual Pyrex capsules and stored under liquid nitrogen for 29 and 39 months. Pre- and post-immersion tests were performed on the propellant and coupons. Tensile properties did not change for either vapor- or liquid-immersed specimens. No significant exposure effects were found by the corrosion mapping, visual, microscopic or scanning electron microscopy (SEM) inspections. Chemical analysis of the off-loaded propellant did not reveal any significant changes due to titanium corrosion. Gravimetric, visual, microscopic, and metallurgical examination with pitting analysis did not reveal gross corrosion of the titanium, although some pitting appeared to be greater after 39 months' exposure. The increase in pit size and the number of pits raised the possibility of unpredictable crack propagation instability. Fracture toughness and stressed coupon tests would be necessary to clear this material for long-term use for pressurized containers.

Titanium alloy 6Al-4V has been investigated for application on a fluorine–hydrazine propulsion system and engineering data were generated for fracture

mechanics, long-term compatibility, ignition and passivation, insulation, and impact sensitivity [355]. The data showed that this alloy should be satisfactory for this application.

The resistance of titanium in water-free liquid fluorine at lower temperatures of <0.3 mm/year is comparable with that of nickel and Monel [316, 317]. However, the corrosion of titanium in gaseous fluorine at 377 K amounts to only 0.0082 mm/year. In spite of their limited resistance against fluorine and HF, very pure molybdenum and tungsten are employed as construction materials in rocket technology because of their great strength at high temperatures if fluorine–hydrogen and fluorine–hydrazine flames are used.

4.2.5 Passivation of Metals in Fluorine

Quite often, passivation of metals can be maintained only if exposure of the metals to air and moisture between fluorine exposures can be avoided. The formation of passivation films with good adherence and minimum sensitivity to air and moisture has been studied extensively for most metals that were qualified for fluorine service.

Tests were conducted to evaluate the effectiveness of cleaning and passivation procedures applied to a valve assembly for fluorine service [356]. The general reaction behavior of fluorine with metal surfaces and contaminants, and cleaning and passivation procedures for systems and components using fluorine-containing oxidizers included: (1) reaction of fluorine system contaminants, (2) impact sensitivity of organic residues left from passivation, (3) corrosive behavior of passivated metal surfaces, (4) gases absorbed on passivated surfaces, and (5) mechanical stability of passivation fluoride films.

Frequently, materials can be eliminated for future use with elemental fluorine by exposing them to HF instead of F_2 . Samples of five different metals were weighed while exposed to 10% HF at 322 K (120 °F) for 300 min.

Fluorination reactions reached completion on stainless steel, nickel, and aluminum alloy surfaces very rapidly [357, 358]. The surface film thickness ranged from 5 to 20 Å and fluoride films grew at the expense of oxide films. The apparent film thickness on copper and Monel surfaces continued to increase slowly over an extended period of time. A study of the composition of passive films formed, and the deleterious effect of atmospheric moisture on passivated surfaces showed that exposure of passive films to a humid atmosphere produced hydrated metal fluorides that caused secondary fluorination reactions upon re-exposure of the surfaces to fluorine. The passive films formed by exposure to chlorine trifluoride and chlorine pentafluoride were comparable in thickness with the films formed by fluorine gas, contained metal chloride species, and were less resistant to humid air attack. Fluorine gas appeared to be the most effective agent for the passivation of metals. Adequate passive films were formed at all pressures within 0.1 to 1.0 atm for a period of 15 to 30 min. A stepwise increase in concentration was unnecessary for the

passivation of metals, and slight deformation of metal surfaces did not destroy the passive films. Most of the passivating procedures developed for elemental fluorine can be equally effectively applied to other non-metallic fluoride oxidizers such as ClF_3 or ClF_5 .

Samples of metal (CRES-316 and Monel 400) powders were first passivated using different techniques under evaluation. Then, 100-g samples of the passivated metal powders under evaluation were placed in a constant-volume bomb, evacuated, and backfilled with fluorine gas. After the apparatus had achieved thermal equilibrium, the pressure decay in the bomb due to fluorine consumption was measured as a function of time for 2–3 h. If a sample did not take up any additional fluorine during this test, it was considered completely passivated [359]. The effects of atmospheric moisture on fluoride films were investigated by making reflection electron diffraction patterns of fluoride films formed on copper before and after exposure to atmospheric moisture.

Even though both liquid fluorine and liquid oxygen are very reactive, most of the common metals are sufficiently resistant for many applications. The compatibility with these oxidizers of alloys of iron, nickel, copper, aluminum, magnesium, titanium, and zirconium was examined and corrosion rate data were compiled from both published and unpublished sources and tabulated [360]. The stimulus required to initiate rapid reactions, or burning of both metals or organic materials by compressive impact, tensile impact, friction, wear, and other mechanisms has to be quantified by experiments. Such experiments can help to identify metals that are less sensitive to impact ignition.

Experience gained over a period of years in the use of metal equipment for the production and handling of fluorine and for the production and shipment of hydrofluoric acid has resulted in construction of durable and reliable production equipment [361]. Unfortunately, none of the common metals or alloys has been found to be universally applicable, and even the nobler metals such as platinum and silver have developed shortcomings under certain conditions. Of the common commercial metals, the nickel–copper alloys such as Monel have been found to be most reliable. However, severe corrosion has been encountered under some conditions. Nickel proved to be excellent for service with fluorine to relatively high temperatures. Mild steel has been used extensively in fluorine cell construction and has proved adequate for the storage and shipment of anhydrous hydrofluoric acid.

4.3 Corrosion of Ceramic Materials in Fluorine

Only a few inorganic compounds that form the base of ceramic materials are resistant toward technical grades of fluorine. Some would be acceptable for use in pure fluorine, but in real life fluorine often contains 0.5 to 1.5% HF, which makes it more corrosive.

α -Alumina is not attacked by fluorine at temperatures up to 1073 K (800°), but finely divided (“activated”) α -alumina does react. Glass can be used for dry and HF-free fluorine; otherwise, it will be etched by HF and opacify. Absolutely HF-free fluorine can be heated in Pyrex glass up to 473 K (200 °C). Asbestos is resistant to fluorine, but only highly purified grades of asbestos can be used.

A summary of the compatibility of other non-metallic materials of construction is provided in Table 11 in [292]. That table also contains some information on organic materials of construction.

At elevated temperatures, even ceramic materials, for instance, mullite-based firebrick, can react with fluorine in a flame reaction. If one aims the flame of a fluorine/hydrogen torch at a firebrick and then turns off the hydrogen supply, the destruction of the brick with fluorine continues as an exothermic reaction [282]. Specialty ceramics manufacturers offer parts made from calcium fluoride that are resistant to fluorine flames up to very high temperatures.

The reactions of ceramics intended as structural materials for chemical lasers with fluorine were studied at very high temperatures and included Al_2O_3 , B_4C , Re, LaB_6 , $\text{LaB}_6\text{-C}$, and $\text{LaB}_6\text{-MoSi}_2$ composites [362, 363]. The mechanisms by which fluorine gasifies solids limit the number of possible fluorine-resistant materials. Alumina gasification reaction kinetics were measured using a low-pressure, transonic microwave discharge flow reactor technique at 2.4 Pa and $1100 < T < 2000$ K. LaB_6 specimens exposed to atmospheric pressure fluorine-rich F_2/H_2 flames reacted with atomic fluorine to form a passivating, white LaF_3 coating. Other ceramics evaluated in a fluorine environment were ZrC and ZrB_2 [364] and HfC and HfB_2 [365].

4.3.1 Corrosion of Ceramic Coatings in Fluorine

Coatings composed of 77 mass-% CaF_2 /23 mass-% LiF fused on IN-750 nickel-based alloy were studied using SEM, X-ray diffraction (XRD), energy-dispersive X-ray spectroscopy and optical microscopic methods [366, 367]. This coating-alloy system had good tribological properties in extreme conditions, such as liquid fluorine. The coating had good adherence and acceptable coating wear life.

4.4 Organic Materials of Construction for the Handling of Fluorine

There are very few organic polymers that are suitable for handling of fluorine. In all these cases, the hydrogen or chlorine in the polymer molecule has to be replaced as completely as possible by fluorine in order to minimize the chance of inadvertent ignition.

4.4.1 Elastomers for Fluorine Service

There are only a few organic polymers that are resistant to fluorine within certain limitations. Hydrogen-containing elastomers, such as polyethylene, polyesters, and phenolic resins, autoignite in gaseous fluorine at room temperature or below. PVC, Plexiglass[®], Neoprene, Viton[®] and a few other materials can be used with limitations. Some of the older literature contains very dubious references, such as the erroneous statement that “red rubber” is compatible with fluorine.

Polytetrafluoroethylene (PTFE; Teflon[®] or Hostaflon-TF[®]) is essentially the only elastomer that is suitable for fluorine service [368]. At sea level pressure, it is compatible with fluorine, but at elevated pressure it may begin to react with fluorine. The upper temperature limit at sea-level pressure is near 473 K (200 °C). Above this temperature, PTFE will be destroyed and converted to gaseous tetrafluoromethane. This reaction can escalate itself to a flame-like reaction. PTFE for fluorine service has to be carefully cleaned and may not contain any contaminants. Already tiny specs of dust or skin grease left behind from a fingerprint are sufficient to cause ignition in fluorine. Friction or rapid compression can also initiate a flame reaction that can be energetic enough to ignite adjacent metal parts. Teflon that has been cleaned with trichloroethylene may absorb and retain some of the solvent, which will then react with fluorine. Teflon containing more than 0.35% trichloroethylene is incompatible with liquid fluorine. Solvent-cleaned Teflon gaskets had to be degassed in a vacuum oven to remove absorbed solvents.

Many fluorine system failures have occurred during flow conditions, although the flow condition itself has not been established as the direct cause of failure in most cases. In one test at NASA Lewis, polytetrafluoroethylene (Teflon) was exposed statically to liquid fluorine at 10.3 MPa (1500 psia) without reaction. The same material when subjected to flow conditions at 345 kPa (50 psia) reacted violently. The fact that Teflon withstood static exposure to liquid fluorine and yet failed in the dynamic test is of particular interest. Metals form a protective fluoride surface film when exposed to fluorine. Teflon, on the other hand, tends to react with fluorine to break down the polymer and form unsaturated low molecular weight fluorocarbons. These fluorocarbons would not adhere to the surface and therefore would be of no value as protective films. It is also possible that a surface impurity could act as a reaction initiator.

Static and dynamic tests were made on the compatibility of gaseous fluorine with various liquids, solid plastics, waxes, and greases at pressures of 10.2 MPa (1500 psig) and room temperature [369]. These tests eliminated many materials from further consideration for use in fluorine systems. Only Teflon and ruby (aluminum oxide) were compatible under the static conditions of the tests at 10.2 MPa. Teflon survived quiescent gaseous fluorine at 10.2 MPa (100 atm) as well as flowing fluorine at 344 kPa (3.4 atm). Further tests under dynamic conditions would be required if the application involves exposure to flowing fluorine. Teflon was resistant to stagnant condition, but flowing fluorine caused rapid decomposition. Besides Teflon, other materials investigated were Kel-F, Fluorolube, and Permatex lubricants and various other elastomers.

Initially, this was only a go/no-go test that did not differentiate between different degrees of reaction and incompatibility. In continuation of this effort, the reactivity of 13 liquids, 11 lubricants, and 20 solids with liquid fluorine was examined at two different pressures [370]. Static tests were made on the compatibility of liquid fluorine with several non-metallic materials at 77 K (–320 °F) and at pressures of 101 kPa and 10.4 MPa (14.7 and 1515 psia). None of the liquids and greases tested was found to be entirely suitable for use in fluorine systems. Polytrifluorochloroethylene and N-43, the formula for which is $(C_4F_9)_3N$, did not react with liquid fluorine at 101 kPa or 10.4 MPa (14.7 or 1515 psia) under static conditions, but they did react when injected into liquid fluorine at 10.4 MPa. They also reacted with gaseous fluorine at 10.4 MPa. Although water did not react with liquid fluorine at 10.4 MPa in this test, it is known to react violently with fluorine under other conditions. The pipe-thread lubricant Q-Seal did not react with liquid fluorine, but did react with gaseous fluorine at 10.4 MPa. The results showed that the compatibility of fluorine with non-metals depends on the state of the fluorine and the system design.

A summary of the results is presented in Table 40, which indicates only whether or not a reaction was observed. Unfortunately, this is insufficient information because the dwell time of the samples was only 10 min. The terms “reaction” and “no reaction”, as they appear in that report were defined as follows: “reaction” means that either a visible explosion or fire took place or that the sample on inspection showed signs of oxidation; “no reaction” means that to the unaided eye, the sample appeared unchanged after exposure to liquid fluorine for approximately 10 min.

Both gaseous and liquid fluorine attacked Teflon more severely when flowing instead of resting. A triangular test sample made of Teflon decomposed rapidly in flowing liquid fluorine and only the pressure drop caused by the inadvertent opening of

a leak prevented the propagation of the reaction to adjacent metal parts. Judging by the deformation of the sample, the strongly exothermic reaction started over the entire surface of the sample and not only on one of its sharp edges. A few liquid samples were injected into liquid F_2 at 10.4 MPa (1500 psig) pressure. Kel-F 10 and 3M N43 reacted; tap water did not react.

Six soft-seal materials were investigated for compatibility with liquid fluorine under dynamic conditions [371]. For test purposes the materials were divided into two groups. Group 1 consisted of a nitroso-rubber specimen and two commercial glass-filled Teflon samples, Fluorogreen E-600 and Fluorobrown. Group 2 contained

bronze-, copper- and nickel-filled Teflon specimens as well as a plain Teflon control sample. The results indicated that limited application can be made in liquid-fluorine systems of the seals tested. One commercially available rotating-vane flowmeter was also tested. Operation of the meter was satisfactory at liquid-fluorine flow rates up to 1.58 kg/s (3.5 lb/s) and pressures up to 414 kPa (60 psia). A valve design that employed a soft-seal material at the flow shutoff interface was successfully tested with liquid fluorine at flow rates up to 0.9 kg/s (2 lb/s) and inlet pressures up to 669 kPa (97 psia). In support of this valve design, a compatibility investigation under dynamic liquid-fluorine conditions was conducted on six soft-seal materials. The materials tested were mainly fluorinated plastics.

The purpose of additional tests was to investigate the feasibility of using fluorine–oxygen mixtures in rocket-propulsion systems containing some non-metallic materials [372]. These are described in a later section on materials compatibility with FLOX mixtures.

The effects of fluorine gas exposure at between 1 and 2 atm pressure at room temperature and in liquid fluorine at cryogenic temperature on some properties of nitroso rubbers (the $\text{CF}_3\text{NO}/\text{CF}_2=\text{CF}_2$ copolymer and the $\text{CF}_3\text{NO}/\text{CF}_2=\text{CF}_2/\text{ON}(\text{CF}_2)_3\text{COOH}$ terpolymer systems and the compounded terpolymers) were examined for mid-term immersion [373]. These polymeric materials are more elastic than polytetrafluoroethylene and do not cold-flow, but they are less compatible for long-term use.

Because the resistance of hardly any of the commercially available elastomers was satisfactory for fluorine service, it was attempted to custom-synthesize polymers that were supposed to be resistant to attack by fluorine [374, 375].

4.4.2 Lubricants

Several lubricants have been tested for possible reactions on contact with gaseous fluorine [369]. At 101 kPa = 1 atm and room temperature, Kel-F[®] (Medium Wax), Kel-F[®] (No. 1 Grease), Fluorolube[®]-LG, and Fluorolube[®]-MG showed no or only minor changes. At 10 MPa = 100 atm or elevated temperatures they reacted and became unusable. Perfluorinated oils or greases are less compatible than solid polytetrafluoroethylene. Vacuum pumps filled with perfluorinated low-volatility oils can be used to pump fluorine-containing gases, but it is advisable to allow the ballast valve to remain open. Permatex[®] is one of the recommended lubricants for threaded joints.

The fluorine uptake of four fluorocarbon greases was studied in a glass apparatus at 373 K (100 °C) and a fluorine pressure of 13.3 kPa (110 mm Hg) [376]. The reactivity varied with the composition of the greases. The lowest fluorine uptake was observed with a grease formulated with polychlorotrifluoroethylene as the base material and a perfluorocarbon filler. When the same base material was retained but the filler was changed to a silica filler, an unacceptably high fluorine uptake was observed.

4.5 Selection of Materials for the Handling of Fluorine

After reviewing the information presented in the preceding chapters, it becomes apparent that there is no universally usable material of construction for fluorine equipment. Each material must be specifically selected for the component in question and the selection depends on the conditions of operation with gaseous or liquid fluorine and if it involves only stagnant fluorine or if it includes the more severe conditions with flowing fluorine. Table 36 at the beginning of this section has already offered additional information on the selection of materials for fluorine service. Table 41 lists recommended materials for construction of components in contact with fluorine.

Table 41: Recommended materials of construction for fluorine.

	Gaseous fluorine	Liquid fluorine
Storage tanks	CRES-304L, CRES-347, Al-61	Monel®, CRES-304L, CRES-347, Al-61
Tubing, flanges, couplings	Stainless steel, Al, Cu, brass	Monel®, Al-60, Inconel®, CRES-300 series

5 Components for Fluorine Service

The corrosion of metals by fluorine is stopped or at least retarded by the formation of a passivating fluoride film. As long as the metal is not flexed or scraped, the protective fluoride film remains in place. It is difficult to select materials for components that are designed to be flexed, such as in bellows, which are usually needed to compensate for contraction and expansion of lines during cooling and warming.

Mechanical stability tests were performed to evaluate the metal fluoride stability on metal bellows of CRES-316, Inconel 625, Al-6061-T6, and copper when exposed to various combinations of flexing, cryoshock, gaseous fluorine, and liquid fluorine conditions [377]. Only trace amounts of the passivating coating were susceptible to flaking

by flexing. Most of the particles recovered after the test came from other parts of the system.

A very thorough evaluation of a design for a liquid fluorine feed system was performed by a team at Douglas Aircraft at their test sites at Gypsum Canyon and Antelope Valley [378–380]. These reports contain a complete and detailed description of all components in the system and metallurgical analysis of the locations where some of the components failed during extensive exposure to liquid fluorine at 77 K and gaseous fluorine at ambient temperature. This is one of the best contractor reports we have found in the NASA inventory. It also contains a bibliography of more than 100 related reports and supporting information.

During the period April 1963 to March 1965, the Air Force Rocket Propulsion Laboratory (AFRPL) designed, built, and operated the AFRPL Fluorine Test Facility [381]. The test facility, used to conduct exploratory development investigations of thrust chamber components, had a testing capability up to 44 kN (10000 lb_f) thrust, 10.34 MPa (1500 psia) chamber pressure; and 300 s continuous firing duration. During this development, new insights were gained into materials compatibility, facility design operation problems, control systems, instrumentation, safety considerations, and safe testing approaches. The report described the test facility with block diagrams and control schematics. Results and experience showed that a fluorine test facility can be successfully operated, both safely and economically.

Ground service equipment was designed that was to perform propellant transfer to the upper stage of a launch vehicle operating on liquid fluorine and liquid hydrogen [382] or with fluorine and any other unspecified fuel [383, 384].

In parallel to the development of a liquid fluorine upper-stage vehicle, the problems associated with the launch facility on the ground must be addressed. A paper described the factors that had to be considered in the design and operation of such ground service equipment [385]. Among the factors discussed were general fluorine system requirements, launch facility requirements, safety considerations, and existing facility modification costs. Specific attention was given to storage and transfer, vapor disposal, leak detection, spills, aborts, range safety, and personnel protection.

A liquid fluorine closed flow loop (for component testing) and a rocket engine test stand have been designed, constructed, and operated for extended periods with very few difficulties [386]. Based upon experience with this system, a new attitude toward the handling of fluorine evolved among the operators. Fluorine may now be handled with confidence so long as its peculiar characteristics are considered and respected. More realistic safety, cleaning, passivation, and testing procedures have been developed during that program.

The electrical signal from temperature sensors, liquid level sensors, and other instrumentation that measures properties of fluorine (gas or liquid) under pressure must be conducted through the pressure shell and cryogenic insulation wrapping of the tank. Leak-tight and corrosion-resistant electrical feedthroughs have been developed for use with fluorine and other corrosive fluids [387, 388].

Rocket engines use fluorine as a liquid, but chemical lasers need fluorine as a gas. The on-side storage of the fluorine may be in liquid form. In order to keep the chemical laser supplied with gaseous fluorine, a fluorine vaporizer has to be operated [389]. Using a modified commercial vaporizer, the system vaporized liquid fluorine during eight chemical laser tests with no malfunctions. The nominal operating parameters were 3.79 MPa (550 psig), 40 g/s flow rate and 20 min operating time. Based upon experience with this system, liquid fluorine can be vaporized continuously in a safe, efficient, and environmentally sound manner.

A very detailed fluorine systems design guidebook is Bluhm [390]. This handbook contains criteria for the design of fluorine feed systems and associated components. Two types of information were presented: (1) information defining general methods, and (2) detailed specifications and procedures. Although the major emphasis has been upon criteria for components exposed to elemental fluorine, the information is also applicable to systems utilizing other cryogenic oxidizers such as FLOX, which contain fluorine as a constituent. It also contains a list of components and instrumentation for the design of fluorine systems and a section on the detection and measurement of fluorine concentrations in the air at the workplace. The use of the word “airborne” does not mean that the systems are carried around in an airplane; the word only means to differentiate flight equipment from ground service equipment (which is not covered in this report).

The most complete guide to components and subsystems design, fabrication, and installation considerations for liquid fluorine and FLOX systems is in a NASA Special Publication [391]. It includes sections on properties of fluorine and FLOX mixtures, compatibility of materials, components and subsystems design, fabrication, and installation considerations, facility design criteria, facility preparation and operating procedures, production and transportation, and personnel safety.

A closed-loop components test facility was built specifically for the testing of components for liquid fluorine (LF₂) service. As of 1968, the large-scale 1890-L (500-gallon) liquid fluorine flow facility in the Mojave Desert, CA, had been operational for over 2 years [392, 393]. Constructed from “off-the-shelf” facility hardware, it was capable of instantaneous flow rates up to 113 kg/s (250 lb/s) for simulation of launch site ground service equipment and missile flight conditions. Unique facility features were: 1) largest known capacity single-propellant flow loop for component and subsystem testing; 2) flange and fitting connections instead of welded connections throughout; 3) dual-wall storage and receiver tanks; and 4) gaseous nitrogen blanket maintained at all times other than leak checking and flow operations. Control consoles were used for remotely controlled flow operations. Pressure and temperature instruments (ambient to 77 K = -196 °C = -320 °F) were used to monitor and provide test data. Testing has included valves, seals, quick disconnects, pressurization subsystems, and small combustors. During the first year of operation, 30 different components have been evaluated. Whenever a dead-ended plumbing section or static cavity was opened for component removal, a white, green,

or yellow corrosion product in powder form was encountered and identified as iron, chromium, nickel or aluminum fluoride. The bulk storage tank held 2265 kg (5000 lb) of LF_2 , the low-pressure tank could hold 1631 kg (3600 lb) at 482 kPa (70 psig), and the high-pressure storage tank could hold 679 kg (1500 lb) LF_2 at 5.17 MPa (750 psig). The best gasket was a combination of soft aluminum (Al-2024-T6) sheath surrounding a Teflon gasket, recessed in a groove, and compressed by a serrated flange surface.

The US National Bureau of Standards determined the physical properties of fluorine over a wide range of temperatures and pressures and developed a special fluorine-compatible apparatus for performing PVT measurements [394].

5.1 Valves for Fluorine Service

The selection of materials for fluorine control equipment (shut-off valves, throttling valves, cavitating venturi) is very difficult because the high flow velocities and metal/metal contacts may result in accelerated corrosion or even accidental ignition [395].

Valves for gaseous fluorine service at low pressures can be made of Monel[®] with a seat or plunger of Teflon[®]. For higher pressures the valve body, the seat, and the plunger must be made of Monel. Designs of valves where metal parts rub against each other should be avoided. At the contact point, the protective layer of metal fluorides is scraped off and enhanced corrosion will result. Valves for liquid fluorine service must not only be compatible with fluorine but must also be able to withstand thermal stress caused by the large differences in temperatures as the system cools down. If the valves are externally covered with ice from condensation of moisture from the atmosphere, it may become difficult to operate them. It is recommended to have redundant valves such that the system can be shut off safely if one valve should get stuck open.

Flight-weight axial flow liquid fluorine shutoff valves with a 5-cm (2-in) bore, incorporating bellows-type dynamic seals and poppet and seat combinations, were designed, developed, fabricated, and tested with liquid fluorine [396]. The valve was an all-metal construction utilizing a copper seat and stainless steel poppet. For qualification tests, the coaxial poppet-type valve was cycled under flow conditions of approximately 9 kg/s (20 lb/s) with an upstream pressure of 1.14 MPa (150 psig). This valve had a proof pressure of 1.65 MPa (225 psig = 240 psia), an external leak rate of $<10^{-7} \text{ cm}^3/\text{s}$, an internal leakage of $<100 \text{ cm}^3/\text{h}$ after 1000 LF_2 full flow cycles, valve opening and closing response times of $<500 \text{ ms}$, and a pressure drop of $<34 \text{ kPa}$ differential ($<5 \text{ psid}$) while flowing 29 kg/s (65 lb_m/s) of liquid fluorine [397].

The inlets to propellant valves are usually protected by filters to retain particles that might get lodged on the valve seat and cause the valve to leak when it is commanded shut. The screen material on the filters has to be compatible with the propellant, which in the case of liquid fluorine is a difficult task. The fluoride film growing on the thin metal wires might cause a narrowing of the passages and increase the pressure drop or embrittle the wires. Similar wire mesh is used in surface tension pro-

pellant management devices in propellant tanks for zero-g operation. The long-term effects of propellant immersion on fine micron stainless steel wire cloth were studied for liquid fluorine, chlorine trifluoride, and mixtures of fluorine and oxygen (FLOX) [398]. Historical screen immersion time durations reported in the literature ranged from 3 months to 7 years.

There are many types of valves available for fluorine service. Some of the valves, such as those used for a static rocket engine test with a fluorine/ammonia rocket engine, can be operated by remote control [399].

A pressure relief valve was designed for protecting fluorine–liquid oxygen ATLAS launch vehicle oxidizer tanks against overpressurization [400].

Because it is difficult to design tight packings for rotating or sliding valve stems, bellows-sealed valves are more reliable for fluorine service [401, 402].

5.2 Flowmeters for Fluorine Service

Flowmeters for gaseous fluorine can be built based on the pressure drop through an orifice, with a manometer measuring the pressure differential across the orifice. A flowmeter of this type is described in Straty [403]. Turbine flowmeters are less suitable for fluorine because the rotary parts (shafts and bearings) have friction at metal–metal contacts. Rotameters have been used for low flow rates and low pressures. The float was made of aluminum or steel and the conical glass tube was made from Pyrex[®] [79]. Two precautions must be taken into consideration: The fluorine gas must be free of HF, because otherwise the glass would become opaque, and the float may change its weight or dimensions owing to fluorine corrosion; thus, the rotameter must be calibrated more frequently than with other gases. The wear of metals in a rotameter was measured under various flow conditions [404].

For liquid fluorine, a flowmeter was developed in which a helical swirl was induced in the liquid stream by a multi-hole plate. At a short but wide bulged section of the tubing, the swirl caused a Teflon-coated steel sphere to spin around a race groove in the wall in circles and each passage of the steel ball was recorded on a magnetic pickup on the outside of the tubing. The steel ball was made of CRES-440C. Over an aggregate running time in liquid fluorine of about 1 h with 900 to 1600 RPM, the weight loss of the 1-g ball was less than 0.25% [395]. Other methods of metering F₂ or HF flows are described in Zima and Doescher [405].

A flowmeter for gaseous F₂ using a nickel filament as a sensing element, similar to the katharometer used in thermoconductivity gas chromatography detectors, was calibrated for several gases [406]. The output voltage of the flowmeter was measured for Ar, N₂, O₂, and F₂ for flow rates between 0 and 400 mL/min at filament currents in the range 50–75 mA. The dependence of output on the thermal conductivity of the gas being measured and on the filament current was investigated. The temperature of the filament could be calculated from measured values of the resistance.

5.3 Pumps for Fluorine Service

Low flow rates of fluorine gas can be pumped with membrane pumps, but the repeated flexing of metals shortens the life of the membranes and they have to be replaced very often. In one membrane pump design, the membranes are driven by a hydraulic system, but the (normal, combustible) hydraulic oil is separated from the fluorine by two additional membranes and the interspace is filled with an inert fluid, such as $C_6F_4(CF_3)_2$ (perfluoroxylene) or antimony pentafluoride [407]. Thus, even if one of the membranes should fail, the hydraulic oil and the fluorine would not come into contact with each other.

Pumps for liquid fluorine are not off-the-shelf items and keeping them lubricated is very difficult [408]. In the 1950s, Bell Aerosystems Company developed a liquid fluorine pump that was made from an aluminum alloy and rotated at 30000 RPM [409]. The packings of the rotary seals had to be replaced repeatedly after only 30 min of operation. Some of these pumps are placed in a position where they are referred to as “boost pumps,” such as when liquid fluorine is fed to a vaporizer under pressure. Rocketdyne developed a prototype liquid fluorine pump [410].

A liquid fluorine pump was designed by the stream-filament method and tested for non-cavitating and cavitating performance under different net positive suction head conditions [411]. It was then tested under high RPM conditions and with an inducer tip speed of 57.3 m/s (188 ft/s) [412, 413].

Rotating and reciprocating positive displacement pumps of various types were studied for pumping liquid fluorine for low-thrust, high-performance rocket engines [414]. Included in the analysis were: centrifugal, Pitot, Barske, Tesla, drag, gear, vane, axial piston, radial piston, diaphragm, and helirotor pump concepts. The centrifugal and gear pumps were carried through detailed design and fabrication. After preliminary testing in Freon 12, the centrifugal pump was selected for further testing and development. It was tested in Freon 12 to obtain the hydrodynamic performance. Tests were also conducted in liquid fluorine to demonstrate chemical compatibility.

The design of rapidly rotating dynamic seals in pumps is a difficult task for both cryogenic oxygen and cryogenic fluorine, but highly complicated for liquid fluorine because of the reactivity of fluorine with gasket and seal materials [415]. Friction and wear studies were conducted with four material combinations submerged in liquid oxygen or in liquid fluorine to determine their potential as dynamic seal components for fluorine turbopumps. The friction and wear experiments were conducted with a hemispherically tipped rider with a radius of 3/16 in sliding in a circumferential path on the flat surface of a rotating disk measuring 21 in in diameter. The seals used in this investigation had a flame-sprayed Al_2O_3 nosepiece (0.006 to 0.008 in thick) and were run against a mating disk of TiC cermet or a fused coating of $CaF_2 + LiF-NiF_2$ on Al_2O_3 submerged in liquid fluorine. Results indicated that fluoride films, either as an applied fused coating ($CaF_2 + LiF + NiF_2$) or as a film formed during sliding (NiF_2 on the TiC cermet or possibly AlF_3 on Al_2O_3) in liquid fluorine, were beneficial

in reducing the friction and wear of the Al_2O_3 riders. The seal experiments in liquid fluorine showed that flame-sprayed Al_2O_3 sliding against the TiC cermet or a fused coating of $\text{CaF}_2 + \text{LiF} + \text{NiF}_2$ on Al_2O_3 are potential LF_2 rotary seal materials.

Converting an ATLAS launch vehicle from operation on LOX to operation on FLOX was motivated by the potential gain in payload and terminal velocity capability, but it was a difficult engineering challenge. Compatibility of FLOX with tankage, pumps, and flow control components was extensively investigated before the program was canceled. The most critical part in the conversion project was the oxidizer pump and its rotary seals [416].

An experimental program was conducted to evaluate and select materials for ball bearings for use in liquid fluorine or FLOX [417]. The ability of three different ball-separator materials, each containing nickel, to form and transfer a nickel fluoride film to provide effective lubrication at the required contact areas of a ball bearing operating in liquid fluorine was evaluated. In addition, solid lubrication of a ball bearing operating in liquid fluorine by either a fused fluoride coating applied to all surfaces of the ball separator, or by fluoride impregnation of porous sintered material ball separators was evaluated. Less bearing wear occurred when tests were conducted in the less reactive FLOX instead of liquid fluorine. Bearings fabricated from any of the materials tested would have only relatively short wear lives and would require frequent replacement in a reusable engine (as opposed to a fly-once-throw-away engine).

Lubricating mechanism, cage design, and design factors of contact seals for liquid fluorine pumps were studied [418].

At a fluorine manufacturing plant, the cylinders to be filled with high-pressure fluorine gas are typically are not pressurized with a compressor, but fluorine is first liquefied into sturdy, pressure-proof cold traps and then allowed to vaporize under its own vapor pressure. This has the advantage that non-volatile contaminants are left behind in the cold trap. However, compressors for gaseous fluorine have been designed for applications where recovered, unreacted gaseous fluorine has to be recycled through a process for another pass through a reactor [419, 420].

5.4 Pressurization Systems for Liquid Fluorine Service

Main tank injection pressurization systems have been tested for several hypergolic propellant combinations. Because fluorine reacts hypergolically with all fuels, fluorine systems would be a good candidate for testing main tank injection pressurization. In the case of

although the reaction takes place mostly on the surface of the liquid propellant, the concern would be about frozen HF particles getting entrained into the lower part of the cryogenic propellant liquid and clogging filters and injection orifices [421–427].

5.5 Pressure Regulators for Fluorine Service

Although a pressurant gas regulator for a pressure-fed rocket using fluorine oxidizer is intended to flow only pressurant gas (helium), fluorine may diffuse back to the regulator membrane and corrode it before it has a chance to fly. A new helium regulator had to be developed for a fluorine propellant system in an upper-stage rocket [428].

5.6 Quick-Disconnect Couplings for Fluorine Service

A prototype “quick-disconnect” coupling for ground-to-vehicle transfer of liquid fluorine was designed, developed, and successfully tested at NASA LRC [371]. Operational features of this hardware included remote positive control of liquid-fluorine flow during the transfer operation, remote connection and separation capabilities, negligible liquid-fluorine spillage upon disconnection of the coupling, and remote reconnection and reuse capability if an abort condition should arise. The design proved satisfactory at flow rates up to 1.13 kg/s (2.5 lb_m/s) and pressure differentials up to 158 kPa differential pressure (23 psid). A commercially available rotating-vane flowmeter was also tested. Operation of the meter was satisfactory at liquid-fluorine flow rates up to 1.58 kg/s (3.5 lb_m/s) and pressures up to 414 kPa (60 psia).

Quick disconnect couplings were developed for use with fluorine and fluorine-containing oxidizers for the ATLAS launch vehicle [429] or a typical upper stage (e.g., NOMAD and for a planned LF₂/LH₂ upper stage) oxidizer fill-and-drain application [430, 431]. Appendix III of van Horn [430] contains a complete summary of materials compatibility with fluorine and chlorine trifluoride.

6 Special Problems During the Use of Fluorine

Like any other hazardous chemical, certain special safety precautions are required for the safe use of fluorine as a rocket or chemical laser propellant [432].

6.1 Controlled Destruction and Disposal of Excess Fluorine

Every once in a while a fluorine user may get stuck with excess fluorine that has been accidentally contaminated or is no longer needed. It is highly unlikely that the supplier would take it back for reprocessing and in most cases the fluorine has to be destroyed at the test site. Contingency planning for a liquid-fluorine test site must assume the worst case scenario where tanks begin leaking and large amounts of fluorine must be destroyed in a controlled and confined manner. In addition, routine transfer of liquid fluorine from one tank to another often requires venting of the receiving tank and the vent gas has to be neutralized. At the end of the transfer, the supply tank has to

be depressurized, venting a mixture of pressurant gas and fluorine. Small amounts of fluorine gas need to be disposed of when new systems are passivated and purged with fluorine. There are only very few geographic locations where fluorine gas can be vented through a tall stack into the atmosphere, as long as a good wind is blowing in the right direction.

Fluorine disposal and destruction processes described here are either dry processes or wet processes. We considered dividing this section into dry, wet, and other processes, but there were several publications that dealt with more than one process that it would be difficult to divide this section by mode of disposal. Instead, it follows the same near-chronological order as most of the other sections in this book.

One method for disposal of excess fluorine (even fluorine contaminated with HF) injected the gas into an air/methane or air/propane ring burner operating on a rich air:fuel ratio [60]. DuPont in Wilmington, DE at one time had a facility of this type that could dispose of 56 kg F₂/h. The burner effluents were first quenched with water in a tower packed with graphite Raschig rings, and then washed with a spray of caustic soda liquid.

The National Advisory Committee for Aeronautics (NACA) Lewis Research Center evaluated several different methods for disposal of excess fluorine [433]. Undesirable fluorine was neutralized by reaction with water, steam, fuel gas or solid absorbents. Many of these earlier methods required continuous control by a well-trained operator, required much floor space, and consumed large quantities of expensive neutralizing chemicals. There was the need for a fluorine disposal method that could operate unattended and would use only readily available, less expensive chemicals. Such a method was found in the reaction of fluorine with activated charcoal that proceeds according to

and quickly leads to tetrafluoromethane without any undesirable by-products. Tetrafluoromethane is not poisonous and can be vented to the atmosphere. It has only a very low ozone depletion potential.

Lignite coal or graphitized coal is not suitable because it may result in the formation of less volatile fluorinated reaction products that may clog the reactor. Graphite reacts with fluorine only above 723 K (450 °C), whereas at lower temperatures it forms an addition (intercalation) product. Activated charcoal must have the necessary porosity and surface area to be reactive with fluorine. The waste gases enter the reaction chamber at the head and leave it at the bottom. The reaction may be so vigorous that it is advisable to dilute pure fluorine with an inert gas so as to extend the useful lifetime of the reactor. The optimal reaction temperature in the reactor depends on the thermal insulation surrounding the reactor and can be controlled by varying the dilution ratio. The reactor has to be kept at a minimum temperature to allow instant destruction of fluorine. The purity and porosity of the activated charcoal determines the ignition temperature. Charcoal (even barbeque briquets)

has a high surface area and absorbs a lot of atmospheric moisture when stored in air in unsealed bags. Excessive moisture content reduces the activity and may delay the start of the reaction. Therefore, it is best to dry the activated charcoal before use. Graphitized carbon reacts only if it is impregnated with an ignition material. While developing the reactor and optimizing the operating conditions, tests were run with fluorine concentrations varying from 0.5 to 100 vol.-%. For instance, when the feed contained 15 vol.-% F_2 , the effluents contained less than 0.003% (30 ppm) residual F_2 . With only 0.5% F_2 in the feed, the conversion was incomplete because the reaction temperature was too low, allowing 138 ppm F_2 to escape unreacted. Adding a little oxygen to the gas feed was recommended to improve the conversion of low fluorine concentrations. For every 5.5 kg fluorine to be destroyed, the reactor will consume 1 kg of activated charcoal. The grain size of the charcoal has to be optimized for the size of the reactor. If the grain size is too small, the pressure drop becomes prohibitively high. On the other hand, small grain size allows more surface area to be exposed to the gas and will result in more complete conversion [303]. The NASA Publication SP-3037, on pages 165–173, shows design examples and a photograph of an actual charcoal fluorine disposal facility [434].

Fluorine disposal reactors have been used extensively at several nuclear reactor fuel processing plants and rocket test sites in the US during the 1960s. The maintenance is relatively simple as one only needs to add more charcoal while the reactor is cold and not in use. If large fluorine flow rates (>10 kg/h) need to be destroyed, several reactors have been operated in parallel. On the other end of the flow rates, a small fluorine disposal unit was developed for laboratory use. It consisted essentially of a Pyrex® glass vessel with a metal screen holding a bed of granular activated charcoal. The progress of the reaction could be observed through the glass wall and the flow rate could be adjusted to keep the flame zone in the upstream part of the bed [304]. Fluorine and fluorine–oxygen and fluorine–nitrogen mixtures containing as little as 6.5 vol.-% fluorine reacted spontaneously with fresh dry charcoal. Fluorine and fluorine–oxygen mixtures were consumed at rates up to 11.3 kg/h (25 lb_m/h) in an experimental portable reactor containing 170 L (6 cubic feet) of charcoal.

The reaction of fluorine with water was reported to potentially proceed in two ways under otherwise identical conditions, one by a smooth uninhibited burning reaction characterized by a purple flame, and the other by a slower, inhibited reaction in which no flame was observed. Violent explosions took place unpredictably when the inhibited reaction suddenly shifted to the burning reaction mode. The reaction of fluorine with low-temperature steam can also be explosive after a delayed start.

In the literature there are several surveys of various techniques for disposal of excess fluorine. One of the cleanest methods is the reaction of fluorine or diluted fluorine with a 200–500% excess above stoichiometric requirements of superheated steam [219, 435, 436]. Air-diluted fluorine with less than 50% F_2 should be preheated to about 672 K (750 °F) before reacting with superheated steam heated to 533–728 K (500–850 °F).

Small reactor units have been designed for fluorine disposal on a laboratory scale [437].

Wood chips, coke, and coconut-shell charcoals were evaluated for fluorine disposal in a reactor [438]. The coconut-shell charcoal produced the smallest amount of solid and liquid reaction products. Efficient removal of fluorine was accomplished by the coconut-shell charcoal in a reactor measuring 12.5 cm (5 in) in diameter with a feed containing 25 vol-% fluorine at flow rates from 2.8 to 11.3 m³/h (100 to 400 scfh) and reactor-wall temperatures of 922 to 1255 K (1200 to 1800 °F).

Carbide & Carbon Chem. Co., then a division of Union Carbide, built a facility for the disposal of large amounts of fluorine, in which fluorine was reacted with a large (2- to 29-fold excess above stoichiometric) amount of superheated steam. In this way, the slow reaction

received the necessary pre-heat to achieve a more rapid and more complete conversion. One must avoid the accumulation of unreacted fluorine and steam because it may result in explosions [224]. Similar reactions take place between oxygen difluoride and steam. High fluorine concentrations in the feed gas may have to be diluted with air to avoid a welding torch-like flame reaction that might melt the apparatus. After complete hydrolysis, the reaction products were quenched in a wash tower with water sprays. The wash tower effluents were collected in a lined holding pond and neutralized with caustic lime. The reactor was made from Monel[®] and the wall temperature was kept at 533 to 673 K (260 to 400 °C). This reactor was more suitable for continuous disposal and required more controls than the activated charcoal reactor. Another facility using sodium hydroxide solution in a counter-flow absorption tower was operating continuously and was capable of destroying 30 kg/day of fluorine, but required complex controls and maintenance and used neutralizing chemicals [439, 440]. In this continuous process, fluorine and HF are absorbed with sodium hydroxide solution (>2% NaOH) and the fluoride-containing nearly exhausted sodium hydroxide solution is reacted with caustic lime slurry (calcium oxide/calcium hydroxide) resulting in insoluble CaF₂, which can settle out in settling ponds and in an NaOH solution, which is pumped back to the F₂/HF absorber

In a similar continuously operating fluorine disposal facility fluorine was reacted with an aqueous solution of 54% NaOH [441, 442]. This design would also be advantageous for treating gases that contain HF in addition to F₂. The fluorine concentration in the effluent was less than 0.02% (still too high for discharge into the air at many locations!). There is also concern that under these conditions, fluorine is only converted

to oxygen difluoride, which is a different problem altogether because it is less reactive than fluorine and more difficult to dispose of.

A review of several candidate methods for disposal of fluorine lists the reaction of fluorine with sodium chloride leading to sodium fluoride and free chlorine [443]. The chlorine can be neutralized as usual with caustic lye and a reducing agent. This avoids the reaction of fluorine with water, which is often inhibited and sometimes starts only explosively after the accumulation of sufficient reactants in a closed vessel. Some investigators did not recommend the charcoal method and alerted their colleagues to the potential formation of graphite fluoride, which can decompose explosively.

There has been no lack of attempts to use anything but the most readily available chemical, water, for the disposal of fluorine, but even if conditions are maintained that allow complete conversion, the question remains about what to do with the dilute HF solutions obtained in this way. See also Houston [10].

Instead of passing the fluorine-containing gas through a packed-bed reactor, it is also possible to pass it through a fluidized-bed reactor [444]. That has the advantage of the suspended solid being continually replaced at the same rate as it is consumed and it avoids hot spots in the reactor. Fluidized bed reactors would only be used for larger installations because they are more complex and are operated continuously.

Alumina, soda lime, and charcoal were evaluated as fluorine disposal media [445]. Plugging of the disposal traps occurred regularly when alumina and soda lime were used. The use of charcoal reduced plugging problems, but a check valve was required to eliminate backflow interference from small pressure surges resulting from the charcoal-fluorine reaction. In a given size trap, charcoal had twice the capacity for fluorine disposal, compared with soda-lime or alumina capacity. Charcoal was selected as the most desirable disposal medium because of its high disposal capacity, gaseous reaction product (CF_4), and freedom from trap plugging. Iron filings and steel wool were tested as a fluorine scavenger [446].

The primary product of the reaction between fluorine and charcoal is CF_4 , with small amounts of higher fluorocarbons. Heated or unheated charcoal traps have been used at several sites for fluorine disposal. Non-activated wood charcoal heated to 398–573 K (125–300 °C) was recommended for fluorine disposal. Explosions were reported with activated charcoals and low fluorine concentrations [447]. The explosions were attributed to the rapid reaction of a large quantity of adsorbed, unreacted fluorine with charcoal after the reaction was initiated by increasing the fluorine concentrations to the ignition point. This hypothesis was confirmed by several observations [448]:

- Non-activated charcoals with low surface areas (and thus lower capacity for fluorine adsorption) did not explode when reacted with fluorine under the same conditions.
- The residual fluorine concentration in unreacted activated charcoal was much higher than that in non-activated charcoal.
- Fluorine adsorbed on activated charcoal could be removed by purging: then the charcoal did not explode when the fluorine concentration was sharply increased.

Published data often do not adequately define trap operating conditions at the time when the problem occurred, such as temperature and fluorine flow, for efficient fluorine disposal. Data for the composition of reaction product gases under various operating conditions are also incomplete. A study was undertaken to clarify these uncertainties. Results indicated that the fluorine–charcoal reaction efficiency increased with temperature. At 5% fluorine in the inlet gas, only 10% of the fluorine reacted with charcoal at 473 K (200 °C). A total flow >25 times higher than in these tests resulted in no fluorine breakthrough at 573 K (300 °C). The effect of charcoal bed depth on F₂ disposal rate needs to be examined. One study demonstrated efficient F₂ disposal with 25% fluorine in a heated charcoal bed, 5 cm (2 in) in diameter and 6.25 cm (2.5 in) deep, at a linear flow speed of 15 m/min (50 ft/min). At 573 K (300 °C), the F₂–charcoal reaction zone was narrow.

A study was performed to determine the best method of disposing of waste fluorine in the effluent from a uranium oxide conversion facility [449]. After reviewing the fluorine disposal literature and upon considering the nuclear safety constraints, it was determined that the two most promising processes were the fluidized alumina bed and the caustic scrubber [450]. To obtain more design data for the latter process, a three-stage, 12.5-cm (5-in) I.D. spray tower was constructed and operated. This unit used a 10% potassium hydroxide solution at scrubbing liquid flows of 5.7 to 11.4 L/min (1.5 to 3 gpm) and achieved a 90% fluorine removal efficiency at fluorine flowrates as high as 15 L/min (4 scfm). However, two toxic by-products, oxygen difluoride and nitroxy fluoride, were detected in the effluent gases. After considering the relative merits of both disposal processes, it was concluded that the fluidized bed is superior, especially if the contaminated waste material (aluminum oxyfluoride) were salable. See also Netzer [451].

6.2 Consequences of Accidental Fluorine Leaks and Spills

Because many materials in and around rocket test sites and rocket launch sites are not designed to be totally compatible with fluorine, a fluorine leak or spill may cause rapid ignition and occasional explosions. Fluorine (both gaseous and liquid) spills have been simulated to obtain a better understanding of the potential consequences of such an accident. This type of testing is an expansion of the materials compatibility tests described earlier. The objective of those tests was to identify materials that are compatible with fluorine in any state (liquid or gaseous) and are designed to be exposed to fluorine for a long time. It is impractical to design the entire test and launch site from such materials; thus, contact with incompatible materials is possible and must be anticipated if static and flight testing with fluorine propellants is conducted. It does not even require an accident; sometimes fluorine has to be vented at the end of a test and those vented gases might come into contact with incompatible materials downwind of the vent stack.

The hypergolicity of cryogenic liquid fluorine or FLOX when spilled in an unconfined manner onto various common materials is of particular interest. Fluorine, FLOX, and their most common byproduct, HF, are all toxic; it is desirable that these gases be inerted or made to rise upward for better dispersion and diffusion into the atmosphere for the safety of personnel and communities downwind of the spill area. An investigation was therefore made to determine the results of such spillages onto various materials. Small quantities (2.2 to 4.5 kg = 5 to 10 lb_m) of liquid (FLOX, fluorine, or oxygen) were spilled from a height of about 51 cm (20 in) upon several common materials that might be found or placed around a test or launch facility [452]. The materials were confined in stainless steel pans (0.9 × 0.9 × 0.3 m = 3 × 3 × 1 ft). Fluorine reacted violently with wet sand or with a puddle of water. The reaction with the water puddle was accompanied by a flash and a loud explosion. When liquid fluorine was spilled upon JP-4, smooth burning occurred, as opposed to the multiple microexplosions with FLOX (Section 10.1.6). From these spill tests, information was obtained in the following areas: (1) The hypergolicity of FLOX and fluorine with various materials upon which they might be spilled; (2) qualitative information on reaction characteristics and combustion propagation by visual observation and high-speed photography; (3) visual, photographic, and cinematographic information on the path of the resultant gas clouds; (4) the feasibility of using charcoal as a reactant for fluorine spills as a means of pollution control. Placing charcoal in areas underneath fluorine pipes where leaks would be suspected is one precaution that can be taken to prevent or mitigate worse disasters.

6.2.1 Neutralization and Treatment of Accidental Fluorine Leaks

6.2.1.1 Evaluation of Neutralization Agents

It is very difficult to deal with fluorine leaks because in many instances the leak is accompanied by a fire within seconds from when it was first detected. There are basically two methods that were tested in various settings: water sprays and dust clouds with sodium carbonate [433, 453]. The various methods were tested in a cubical test chamber that was lined with asbestos, but not hermetically sealed so that overpressure would be vented to the atmosphere. On the ceiling of the chamber was a circular manifold showerhead through which water was sprayed on the leak. Sodium carbonate was blown from a tray along the ceiling with compressed air. There was an array of previously evacuated cylinders into which samples of the atmosphere in the test chamber could be collected at various stages of the experiment to obtain a concentration–time profile. Six tests were conducted with this apparatus, three with gaseous and three with liquid fluorine leaking out. The tests with gaseous fluorine did not produce overpressure or light emission as external signs of a reaction, but liquid fluorine caused overpressure in the chamber and flashes of light. The walls of the chamber were partially destroyed. The results are illustrated in Figure 17 and 18. Figure 17 shows the distribution of fluorine between the absorption media and the surrounding atmosphere.

Figure 18 shows the time profile of the fluorine concentration in the test chamber. One can see that the absorption of gaseous fluorine is less complete than that of liquid fluorine.

Figure 17: Absorption tests of gaseous and liquid fluorine with water and sodium carbonate. (From [433].)

Figure 18: Fluorine concentration in the test chamber atmosphere following the application of water or soda. (From [433].)

In tests with liquid fluorine the concentration was quickly brought down to levels where ignition was no longer a hazard. The application of soda powder was at least as effective as the application of water spray. In a seventh test, liquid fluorine was spilled without any absorbent. The spill ignited and destroyed the test stand. The fluorine vapor cloud extended for several miles downwind.

Water and soda ash were investigated for use as deluge agents to reduce contamination from fluorine spills [454]. Thirty to forty percent of the released fluorine was captured by these agents. The reactions were rapid. However, no damage to the test structure was noted. Fine water sprays were more effective reactants than coarse water sprays.

Thirty-eight different chemicals in addition to water and sodium carbonate were tested for their effectiveness for the neutralization of fluorine spills [453]. The requirements for such chemicals are:

1. large absorption capacity for fluorine
2. fast, but not explosive reaction with fluorine
3. no formation of toxic reaction products
4. no hygroscopy and no tendency to cake during storage.

Three different test methods were used to evaluate the various chemicals. In series A, small quantities of the material were added to 4 mL of liquid fluorine in a test tube. Only $\text{Ca}(\text{OH})_2$, CaCO_3 , NaHCO_3 , Na_2CO_3 , $\text{Na}_2\text{B}_4\text{O}_7$, K_2CO_3 , and KF showed useful absorption properties. In series B, an excess of the materials that passed the requirements of Series A was held in a 250-mL beaker and 6 g liquid fluorine were poured on the pile. In this series, an aqueous suspension of CaCO_3 , solid NaHCO_3 , $\text{Na}_2\text{B}_4\text{O}_7$, Na_2CO_3 , or K_2CO_3 had the best absorption properties. Test series C simulated the conditions of an accidental fluorine leak where the absorbent was dumped on the evaporating fluorine. A fire extinguisher capable of holding 450 kg dry powder was converted for this test and recharged with the powder under test. The fire extinguisher was pressurized with nitrogen to 1414 kPa (14 atm = 205 psia) and capable of applying 360 kg/min. The powder was applied to the leak through a bifurcated manifold that was aimed at the leak from two different sides. The best neutralization was achieved with NaHCO_3 , Na_2CO_3 , and K_2CO_3 . It is assumed that soda was used as the monohydrate $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$. Potassium carbonate was less suitable because it is very hygroscopic and may clump together during storage. See also Chamberlain and Siegmund [455, 456].

The USAF conducted fluorine spill neutralization tests on an even grander scale, again using water and soda as the main agents [457]. The objective of these tests was to determine how spilled fluorine in quantities of several hundred kilograms can be neutralized by water or soda and how the unreacted fluorine escapes and spreads in the area. A test site was selected at the boundary of Edwards Air Force Base in the Mojave Desert away from any inhabited areas where open liquid fluorine pools could be dumped with soda powder or sprayed with water sprays. Two tests were conducted,

one with soda and one with water and each used 110 kg of liquid fluorine. The test chamber was less confined than the one used at NASA, such that hot gases could escape more rapidly. In another large-scale test, 730 kg of liquid fluorine were sprayed with 1200 kg of water. The wind speed at the moment of the test was 5 to 7 knots. This was less than desirable, but resulted in gradual dispersion of the downwind plume. Water reacted vigorously with a bright flame with the fluorine, similar to what had already been observed by earlier experimenters. Numerous gas sampling stations were installed at ground level in the downwind area and it was noted that the gases were diluted to non-hazardous concentrations after traveling 1.6 km in downwind direction. The hot HF had substantial buoyancy and rose at the accident site. Groups of white rats were caged and exposed to the plume at 3, 22, 45, 75, and 150 m from the test site. The animals at 3 and 22 m suffered mainly scalding from the heat of reaction and chemical burns were only secondary. Concentrations above ground level were measured by sampling lines dangling from a helicopter, but only in one of the tests. The largest test ever of this kind used 750 kg of liquid fluorine and 6 metric tons of soda. For comparison, a parallel test was conducted with 485 kg of liquid fluorine without any absorbing media applied. In this test, the stainless steel bath tub holding the fluorine ignited and half of it burned, forming yellow fumes (FeF_3).

The cheapest method for neutralizing larger fluorine leaks is without any doubt the use of water sprays. However, it is difficult to reproducibly achieve good absorption of fluorine because the reaction proceeds at different rates, depending on the mixture ratio. If small amounts of fluorine are flooded with water, the gas may only be dissolved, but not reacted.

6.2.1.2 Dispersion of Plumes from Fluorine Spills

The distribution of fluorine gas outside a fluorine spill test chamber, with moistened indicator paper giving a semi-quantitative indication is shown in Figure 19, which gives the fluorine plume shape in the vicinity of a spill test chamber and the different shades indicate the local fluorine concentration in relative units (worst = 100).

Atmospheric diffusion tests were conducted to determine the plume trajectory and downwind 3-D concentration profile for combusting and non-combusting fluorine spills under a variety of atmospheric conditions [458]. The trajectory of a hot conflagration cloud resulting from spills of up to 1360 kg (3000 lb) of a 30% LF_2 /70% LOX FLOX/RP-1 mixture was determined by photographic recording and compared with predictions from a computer model. Two F_2 and two HF atmospheric samplers were placed in strategic locations. In a separate test, the evaporation rate of FLOX from a simulated spill containment system was determined. In another test, the blast overpressure caused by a FLOX/RP-1 deflagration was measured. The rate of dispersal of a toxic vapor cloud would depend on meteorological atmospheric conditions at the accident site [459, 460].

Because of the need to develop contingency planning to manage potential accidents involving the release of either HF or fluorine, dispersion models have been de-

Figure 19: Relative fluorine distribution in the test area following a leak of 3 kg fluorine gas and application of water spray. (From [433].)

Test No. 2. Wind from NNW with 8 to 10 knots

veloped and integrated into the Air Force Dispersion Assessment Model (ADAM) system [461, 462]. The thermodynamic aspects of the HF polymerization reaction and dissociation when mixed with air have been modeled and considered in dispersion calculations. The dispersion results have been compared with test results from the Goldfish Series of field tests. The agreement was good between predicted and measured parameters such as cloud temperature, cloud width, and downwind concentration. The mixing of spilled liquid and evaporated gaseous fluorine with ambient air has been modeled, and dispersion results for fluorine were presented. However, owing to the absence of any field data, no verification of predicted results was possible.

The fireball resulting from a launch mishap of a FLOX/kerosene-fueled rocket would quickly disperse the unreacted fluorine and the thermal updraft from the fire would carry it into the upper atmosphere [463].

6.2.1.3 Extinguishment of Fluorine-Supported Fires

It is illusionary to attempt to extinguish a fire that is supported by fluorine and combustible materials. The extremely exothermic reaction cannot be suppressed by any other chemical. Fires supported by a stream of fluorine cannot be extinguished and the fire-fighting crew cannot approach the source without exposing themselves to extreme danger. In many cases one can only stand by, observe from a safe distance and wait for the end of the reaction. Only then the fire-fighting crew can move in and attack the secondary, air-supported fires ignited by the accident. Some authors warn the fire crew not to apply water to liquid fluorine spills owing to an explosion hazard. The use of carbon tetrachloride in fire extinguishers like those that were at one time used for

electrical fires is not recommended either because it was noted that fluorine can react explosively with CCl_4 (Table XI in [292]), also [369]. Because even fluorine leaks that did not result in a fire are best treated with soda powder dispensers, the same method should continue to be used after a fire has erupted.

6.3 Impact-Ignition Sensitivity of Metals in Liquid Fluorine

The impact sensitivity of titanium in LOX or NTO has been well known, and similar sensitivity exists with titanium (or aluminum) sheared while immersed in liquid fluorine [464]. The impact ignition sensitivity of Ti-6Al-4V in liquid fluorine or liquid chlorine pentafluoride was tested under cryogenic conditions and compared with that in LOX [465].

Certain materials immersed in liquid fluorine or fluorine-containing liquid propellants exploded or ignited when subjected to impact or shock loading. The pressure waves resulting from such impact loading may cause microstructural changes in the interior of materials. Under shock loading, tantalum, columbium, and titanium alloys exhibited discoloration on the specimen surface and dislocation cell structures within crystalline grains throughout the specimen [466]. Commercial polytetrafluorethylene often caused explosive reactions. The shock waves propagating through the PTFE specimen caused pronounced microstructural changes by the formation of microvoids and spherulites. Electron microscopic studies revealed that these spherulites consist of regular arrays of thin (200 to 300 Å) blade-like lamellae containing segments measuring 20 Å wide.

A remotely operated open-cup impact tester for studying impact initiation of reaction of various liquid fluorinating agents with metals and plastics was developed that was similar to an apparatus used to study the impact sensitivity of metals and plastics materials immersed in LOX [467].

It may not always require a strong mechanical impact shock to initiate reactions of fluorine with metals. Sudden gas pressure increases may cause adiabatic heating and ignition. Accidental ignitions have been observed in industrial applications of fluorine or nitrogen trifluoride for cleaning of semiconductor processing equipment [468].

6.4 Absorption of HF Fumes from Rocket Engine Tests with Fluorine Oxidizers

The testing of rocket engines with fluorine-containing oxidizers is substantially complicated by the need to effectively absorb the HF-containing exhaust gases for the safety of the test crew and to meet environmental pollution restrictions. The methods for absorption of HF in the exhaust from rocket engines during static tests on the ground will be discussed in *Encyclopedia of Hypergolic Bipropellant Combinations*.

7 Handling Procedures and Equipment for Fluorine

In my opinion the hazards of work with fluorine and its compounds have been greatly overrated. When treated with the respect which is due to it, fluorine is just another substance.

George Cady, discoverer of nitroxyl fluoride NO_3F , 1947

As a result of its extreme reactivity, strong corrosive power, and extreme toxicity, the handling of fluorine poses unique problems and requires extensive precautions, but it can be done safely with the proper training of personnel and an adequate budget for hazard mitigation.

Since the very first suggestion regarding using fluorine as a rocket propellant, there have been numerous publications calculating the theoretical performance of combinations with fluorine as the oxidizer (also to be discussed in *Encyclopedia of Hypergolic Bipropellant Combinations*). The high specific impulse numbers are intriguing and may justify the extra effort (mostly past effort) to bring this oxidizer to practical application. Authors with industrial experience looked at more realistic questions about how this material should be stored, transported, pumped, analyzed, and disposed of [469]. Even chemical companies who were eager to start selling fluorine for rocket applications in the 1960s would readily admit that the handling of fluorine was not an easy task and they offered assistance to their customers to make sure that this was done safely.

In the 1960s there was a lot of discussion about the pros and cons of using a highly corrosive and extremely toxic propellant such as fluorine in rocket engines. This discussion has somewhat settled down since toward the end of the twentieth century, the drive was more toward environmentally friendly propellants and not so much for extreme specific impulses. It is highly unlikely that NASA in its current mode of operation would consider resuming work with fluorine propellants.

For the initial years after WW-II, the US Government did not seem to be interested in actually testing fluorine as a rocket propellant because in those days the fluorine output was almost exclusively earmarked for UF_6 production and increasing the nation's stockpile of nuclear weapons (or starting commercial nuclear power plants using partially enriched uranium). It seems that some of the first rocket engine tests with fluorine were conducted at Rocketdyne in the early 1950s. The NACA

Lewis Flight Propulsion Center, Cleveland, OH, established a test site for fluorine propellants that was equipped with adequate HF scrubbers to minimize environmental pollution. Bell Aircraft Corp. started development of a fluorine engine in 1956 under a contract from the US Air Force [353]. It was estimated that the three locations had conducted more than 500 engine tests and had consumed 30 metric tons of fluorine between the years 1956 and 1960 without major accidents. Typical feed pressure for these tests was 3400 kPa (34 atm) and the flow rate was of the order of 32 kg/s, with local flow velocities up to 30 m/s, depending on the width of the tubing in the feed

system and injectors. US industry even started on the development of a turbo pump that could pump liquid fluorine at very high pressures and flow rates.

Rocketdyne developed the engine for the NOMAD upper stage using liquid fluorine oxidizer and liquid hydrazine fuel and within 2 years of testing they had consumed 500 metric tons of liquid fluorine [470]. Unfortunately, NOMAD did not get to fly.

In Germany, the Bölkow Company (Ottobrunn) started testing with small liquid fluorine/liquid hydrogen engines in the 1960s [471].

The JPL compiled an excellent summary on the experience with fluorine and its safe use as a propellant, in this case for the planned use of liquid fluorine or storable fluorinated oxidizers for upper stages and/or spacecraft to be launched as payloads from the Space Shuttle payload bay [472]. This detailed report with numerous literature references contained sections on experience gained in handling fluorine for nuclear isotope separation and rocket engine ground testing, materials compatibility, component selection, ground service equipment, handling precautions, toxicity, and recommended operating procedures for loading (and unloading, if necessary) fluorine on the Space Shuttle.

Additional information on the safe handling of fluorine can be found in the references listed in Table 42.

In one statement, the company with the most experience in production and handling of liquid fluorine, Allied Chemical Corporation, disagreed with arguments that the hazards of working with fluorine are too high for using it as a rocket propellant. They emphasized that elemental fluorine had been produced at Allied Chemical for almost 18 years and they believed the hazards of working with it were greatly exaggerated

by fluorine foes. They admitted that the use of fluorine and FLOX is not entirely free of problems. However, they also believed that those problems were not insurmountable. Similar problems were faced earlier with other propellants such as dinitrogen tetroxide, and were subsequently solved.

7.1 Personnel Protection Suits for Fluorine Propellant Handlers

Based on 15 years of experience with handling liquid fluorine at rocket test sites, the safety clothing and equipment listed in Table 43 were recommended for different work situations.

Table 43: Recommended protective clothing and safety equipment for fluorine workers.

When the condition is, or is expected to be, one in which:	Recommended safety clothing and equipment
There is no odor of fluorine (less than 0.10 ppm fluorine in air)	Common work clothes
Fluorine can be smelled, but does not irritate the nose (0.10 to 15 ppm fluorine in air)	Easily removable plastic gloves, face shield, cloth head covering, work clothes; avoid staying in the area longer than 1/2 h
Fluorine irritates the nose, but does not affect the skin or hair (15 to 100 ppm fluorine in air)	Filtered-air mask or portable air supply, easily removable plastic gloves, face shield, cloth or plastic head covering, and loose-fitting plastic jacket; minimize time in the area
Fluorine warms the skin and makes body hair sticky (above 100 ppm fluorine in air)	Full safety suit (preferably made of a fluoropolymer) and breathing-air supply
Rescue, standby, or accident surveillance as needed	Full safety suit and breathing-air supply

Data source: [480]

Different types of protective gear would apply to workers in fluorine production factories where the presence of HF and hot electrolyte would add to the inhalation, burn, and skin splash hazards.

A prototype propellant handler's suit for protection against gaseous fluorine and liquid chlorine trifluoride was tested and exposed to the chemicals (without operators in them) [481]. The exposed components of this garment were made of perfluoropolymers and stainless steel. The complete suit and sample components were exposed to both gaseous fluorine and liquid chlorine trifluoride, but the suit reacted with liquid chlorine trifluoride and therefore failed to pass the operational test.

As part of the evaluation of protective clothing for use with fluorine, the following test program was conducted: **(1)** chemical compatibility; **(2)** gaseous permeation;

(3) gaseous impingement; (4) physical property deterioration; (5) liquid impingement [482]. Materials that passed the initial test (chemical compatibility) were subsequently tested for permeability and physical property deterioration. Forty-seven possible protective suit materials were selected for the test. These included neoprenes, cellulose-acetate, Teflon, polyurethanes, butyls, Vitons, and metalized coated laminates of various types. A total of 11 materials were compatible with gaseous fluorine. These sample materials were impinged with liquid fluorine. A total of 24 samples were liquid impinged, and some were re-tested to verify results. The liquid fluorine tests involved impinging the samples, which were mounted on a stainless steel stand, with approximately 50 mL of liquid fluorine per sample, 2.5 cm (1 in) from a 1.5-mm (1/16 in) jet orifice to the surface of the sample, at 344 kPa (50 psig), and exposed for 5–8 s.

For the evaluation of protective clothing for handling fluorine, see [483, 484].

7.2 Accident History with Fluorine

With the high reactivity of fluorine, it was unavoidable that there would be occasional accidents. Unfortunately, these accidents are not well documented in the literature.

An typical incident took place at the JPL, where the standard procedures were not followed in this instance. As a result, liquid fluorine was trapped between two valves and pressure increased (a normal occurrence in any cryogenic system). Technicians nearby first heard sharp cracks. A facility valve and line leaked, spraying fluorine on a flowmeter, and a fire was initiated. Automatic shutoff precluded any extensive damage [472].

Figure 20 shows a section of Monel tubing after an explosion with liquid fluorine.

Figure 20: Section of Monel tubing after explosion with liquid fluorine. (From [282].)

7.3 Storage of Gaseous and Liquid Fluorine

The storage of gaseous fluorine in steel cylinders was eventually mastered in the early 1950s and fluorine has been available commercially ever since [485]. At the manufacturing plant, the cylinders are not pressurized with a compressor, but fluorine is first liquefied into sturdy, pressure-proof cold traps and then allowed to vaporize under its own vapor pressure. This has the advantage that non-volatile contaminants are left behind in the cold trap.

For storage of liquid fluorine, double-jacketed, vacuum-jacketed tanks have been developed where the inner chamber can be filled with liquid nitrogen and the outer jacket is evacuated. Similar tanks are used for the transport of liquid fluorine and are described in more detail in the following section. Siting plans for liquid fluorine tanks must consider the distance to populated areas and inhabited buildings. For safety reasons, the cryogenic tanks may be located in underground bunkers or covered areas to minimize heating due to solar radiation.

A unique hazard is the inadvertent formation of mixtures of water ice and liquid fluorine. Such mixtures at 77 K ($-196^{\circ}\text{C} = -320^{\circ}\text{F}$) are shock sensitive and detonable [486]. The ice was tested in two forms: frost crystals and continuous film. No difference in behavior was noted. When liquid fluorine was added to ice at 77 K (-320°F) and then allowed to evaporate, no reaction between the components was observed. The results of the tests indicated that the liquid fluorine/water ice system is very hazardous and must be handled with extreme care. Leakage of moist air or water into a system that contains or will contain liquid fluorine results in the formation of ice and thus an impact-sensitive condition.

A small triple-walled liquid fluorine tank capable of self-pressurizing to 4.1 MPa (600 psia) pressure was made of nickel on the inside and Monel on the outside [395]. As long as the tank was kept dry, there was no corrosion on the nickel tank. Appreciable nickel fluoride deposits, however, resulted when water was not carefully removed. On the basis of that experience, nickel is inferior to Monel as a liquid fluorine container because of its susceptibility to attack by hydrofluoric acid.

7.4 Transportation of Liquid Fluorine

The reactivity of fluorine and the large number of accidents in the early years in handling, storing, and transporting fluorine as a compressed gas have delayed the availability of fluorine as a commercial product. It was not until 1949 that the chemical industry in the UK was confident enough to offer fluorine as a compressed gas in cylinders, and it was predicted that it could be handled with the same ease as elemental chlorine [487].

The largest size cylinder for shipping gaseous fluorine as compressed gas contains only six pounds of the gas at a maximum pressure of 2.7 MPa = 400 psi, which virtually

precluded shipment economically and use in large tonnage quantities at a time when much fluorine was used in the nuclear industry. In 1957, the Interstate Commerce Commission (ICC) in the USA granted a special permit for the shipment of liquid fluorine in an ICC-licensed tank system, making it economically feasible to ship tonnage quantities of fluorine. Since then, in the US, liquid fluorine has been transported by road in tank cars holding 1100, 2300 or 4400 kg fluorine and in railroad tank cars holding 10 to 20 metric tons. These tanks have three walls: the interior wall is made from Monel, and the center and outer walls are made from stainless steel. Liquid nitrogen is filled into the space between the inner two walls in order to keep the hazardous and volatile cargo in the liquid state and at low pressures. The outer chamber is evacuated. For the transport of any cryogenic liquid it is preferred to cool the liquid to below its normal boiling point to minimize vaporization losses during transit. In the case of fluorine, this requirement is much more restrictive, as the tank cannot be vented during transit. Fluorine transport tanks would require an active cooling coil, a reflux condenser, or a cooling jacket filled with a cryogenic, inert liquid that boils below the boiling point of fluorine. The cooling with a jacket of liquid fluorine makes the storage and transport of fluorine independent of mechanical cooling aggregates. The lower boiling point of liquid nitrogen (N_2 : 77.3 K = -195.8°C ; F_2 : 84.8 K = -188.3°C) allows the safe storage and transport of liquid fluorine as long as sufficient liquid nitrogen is available in the outer jacket.

The filling of tank cars can be conducted by personnel that wear only a face shield and rubber clothing, but they do not need to wear a gas mask or respirator at all times (Figure 21). The personnel are trained on how to quickly don gas masks or respirators as soon as the need arises.

The sequence for filling a tank car with liquid fluorine is as follows. First the tank car is checked for leaks and the prior filling status (residual fluorine?) is verified. Then, the inner jacket is filled with liquid nitrogen. This may allow the pressure in the outer vacuum jacket to drop further (which is desirable) as the wall now acts like a cryopanel. In Figure 21, the rear tank car is being filled with liquid nitrogen and the front tank car is being filled with liquid fluorine. The transfer of liquid fluorine from a storage tank into a transport tank and vice versa is achieved by pressurizing with helium. The fleet of tank cars logged 120000 km on public highways in the years from 1956 to 1961 without any severe accidents. At normal (non-desert) ambient temperatures a load of nitrogen will last for 30 days. After this time, the liquid nitrogen has to be refilled or the fluorine overpressure has to be vented, not a pleasant task under any condition. The fluorine tank is hermetically sealed and during normal operation would not be vented to the atmosphere.

A very good summary on handling, transport, and storage of fluorine is contained in [488]. Detailed instructions for unloading a truckload of liquid fluorine are provided in [489].

The inner Monel tank is generally designed for an internal pressure of 485 kPa (4.8 atm) and for an external pressure (from the liquid nitrogen side) of 303 kPa (3 atm).

Figure 21: Filling station for tank cars with liquid fluorine. (Photo courtesy of Allied Chemical.)

The liquid nitrogen jacket is designed for an internal pressure of 303 kPa (3 atm). The outermost tank wall needs to withstand external atmospheric pressure (vacuum on the inside) and is also the attachment for road vibrations and loads created by the mass of the internal tanks. The number of connecting, load-bearing members between the three tank walls has to be minimized as they also act as heat leakage paths.

Over the years (up until 1966), Allied Chemical had designed and built at least three different types of liquid fluorine tanks ([453]). The first two types followed the design described above, with the inner tank and the plumbing made from Monel[®], and the outer tank walls from stainless steel CRES-304. A tank designed later used a carbon-containing steel for the outer wall. All tanks complied with the American Society of Mechanical Engineers pressurized vessel code. The larger transport tank held 2300 kg of liquid fluorine and with a fresh load of liquid nitrogen it could be stored for 25 days without maintenance. The rate of LN₂ evaporation depended on the quality of the vacuum in the outer jacket. The pressure in the vacuum jacket should not exceed $6.6 \text{ Pa} = 5 \times 10^{-2} \text{ mm Hg}$.

If the LN₂ level in the inner jacket should drop to a critical level, a warning signal would sound. If the LN₂ was lost for some unforeseen reason, the inner fluorine tank would remain without noticeable pressure rise for 24 h. It would take another 4 days before the pressure in the fluorine tank reached a critical level. This was considered to be sufficient time to bring in a refill of LN₂ or take other safety precautions. If no new LN₂ can be brought in, the rate of evaporation would be 0.7 kg/h. One would have to evacuate the downwind area. If a leaky vacuum jacket aggravates the problem, the rate

of evaporation can increase to 3.7 kg/h. In the 1960s, tank cars of this type were used by Allied Chemical to transport fluorine from its production facilities at Baton Rouge, LA, and Metropolis, IL, to the rocket test sites of NASA, USAF, and other government and industrial customers. The transports required a special permit from the ICC and were subjected to stringent inspections to make sure that all safety precautions were complied with.

In tests of a portable tank specially designed and constructed under Air Force Contract AF33(616)-2229, liquid fluorine was safely transported and stored [490]. The operation included 82 h of transportation with a total storage time of 2570 h.

Until 1987, USAF transported LF_2 under Department of Transportation (DOT) Exemption DOT E-1479. In later revisions of DOT E-1479 and E-3121, DOT placed several additional requirements upon USAF as a requirement for re-issuance of the exemptions. The new requirements included an emergency response plan, risk assessments, updates for highway routes of movement, and periodic updates of the risk assessments to ensure that routes remain the safest possible.

7.5 Transfer and Pumping of Fluorine

As already mentioned, the most frequently used method for the transfer of liquid fluorine from one tank into another is by pressurization with helium. Additional information can be found in [488]. The tubing is generally made of copper. For larger diameter ($>5\text{ cm} = >2\text{ in.}$) ducts one may use stainless steel. Flanged connections should be avoided as they are prone to leakage. Crush gaskets can be made of aluminum, copper, or annealed nickel. Teflon should be used only as a secondary sealing barrier. Figure 22 gives a plumbing schematic for the transfer of liquid fluorine between two containers using helium gas as the pressurant.

The gas displaced from the tank being filled, a mixture of fluorine and pressurant gas, must be vented from time to time to maintain a pressure differential between the two tanks. The toxic gas is vented into a stack with a propane burner (but that still generates toxic HF). The transfer of a load of 2300 kg of liquid fluorine through a 2.5-cm (1 in) I.D. line with a differential pressure of 100 to 140 kPa may take up to 1 h.

Prior to the first use of a fluorine tankage system, all components need to be thoroughly cleaned and slowly passivated with gaseous fluorine. For proper passivation, the inert gas (nitrogen) in a system is gradually replaced with gaseous fluorine, with 10-min holds programmed in the gradual increase of fluorine partial pressure. After the full fluorine concentration is achieved, the system can be pressurized to the nominal operating pressure and held at that pressure for 12 to 24 h to allow complete passivation to take place. Throughout this procedure the system should be checked for leaks. If the system was not thoroughly cleaned to start with, the combustion of a local contaminant can initiate a metal combustion reaction, which may consume the entire

Figure 22: Transfer of liquid fluorine under helium pressure. (Reproduced from [453]; Allied Chemical.)

system and just leave a heap of fluorides and molten metal. This disastrous reaction cannot be stopped by conventional fire extinguishing methods.

When transferring cryogenic fluids from one tank to another, the evaporating liquid used to cool down lines and tank walls of the receiving tank is usually vented to the atmosphere. In the case of fluorine, this may not be an option. Therefore, a no-vent transfer system has been developed for liquid fluorine [491, 492]. The no-vent loading of a propellant tank is basically a non-adiabatic compression of the ullage gas. Initial tests were conducted with liquid nitrogen as an inert substitute in a 113-L (30-gallon) tank, and later tests were performed with liquid fluorine in a 625-L (165-gallon) tank. For a flight weight system, loading time of 15–20 min. and tank pressure of 483 kPa (70 psia) was the nominal condition. Nine test runs were performed with LF_2 with different loading rates and different initial gas compositions in the ullage (helium or helium/fluorine mixtures). Negative pressure in the receiving tank had to be avoided because it might implode and collapse. Loading was terminated when the 5% ullage point was reached.

8 Physiological and Toxic Effects of Fluorine and HF

Traces of fluoride (NOT elemental fluorine) in drinking water or food supplements are essential for the development of healthy teeth. The hydroxyl group in hydroxylapatite, the main constituent of tooth enamel, is readily exchanged for fluoride because this is one of the first known natural ion exchange column packing materials for fluoride analysis. For some industrial applications, the fluoride contained in drinking water has an adverse effect and fluoride has to be removed from drinking water before the water can be used in chemical processes. Hydroxylapatite would be one of the choice materials for this purpose. High-surface area α -alumina has been used as well.

For the fluoridation of drinking water, fluoride is usually added in the form of hexafluorosilicic acid H_2SiF_6 . The fluoridation of drinking water is a controversial subject and the discussion is still raging in many communities as to whether their drinking water should be fluoridated or not. If it seems that the beneficiaries of fluoridation are only children below the age of 13 years, then, why should the drinking water for the entire population be fluoridated? Others claim that the concentration of fluoride in the drinking water required to have a beneficial effect is too close to the concentration of beginning toxic effects. Other scientists point out that the drinking water in many communities naturally already contains sufficient fluoride so that a statistically significant reduction of tooth decay can be proven for periods even before any fluoride was added to the drinking water in other communities. Several periodicals (called “Fluoride” and “Journal of International Society for Fluoride Research”) are devoted exclusively to the health issues surrounding fluorides.

Summaries on fluorine toxicity have been published by other organizations on several occasions [493–495].

A concise account of the clinical and metabolic consequences of chronic endemic and acute exposure to a wide range of inorganic fluorine compounds and a review of adverse effects on humans following exposure, including case histories of established fluorosis, is given in [496]. A useful summary is also presented of the recommendations of various Public Health Authorities relating to maximum permissible levels of fluorides in the atmosphere and in drinking water.

A very comprehensive summary of the physiological and toxic effects of fluorine and fluorine compounds (particularly HF) is available in the monograph by [497]. It deals predominantly with damages caused by the flue gases from aluminum smelters and phosphate fertilizer factories. Anybody who is tasked with the design of fluorine test facilities (rockets or lasers) should familiarize themselves with the possible damages to surrounding populations, animals, and vegetation.

8.1 Olfactory Threshold for Fluorine Gas

Fluorine has a characteristic pungent odor, detectable in concentrations as low as 20 ppb, which is below the safe long-term workplace exposure level. The American Conference of Governmental Industrial Hygienists (ACGIH) recommended maximum allowable concentration for a daily 8-h time-weighted exposure is 1 ppm (see Section 8.2 on the toxicity of fluorine).

Fluorine has such a sharp, penetrating odor that inhalation of toxic quantities is unlikely unless the individual is trapped in a location from which escape is impossible. If the fluorine odor is irritating to the nasal passages, this indicates a sizeable leak and the area should be evacuated immediately. The odor of fluorine becomes annoying or irritating to the nose at about 18 to 27 ppm. As soon as such irritation is noticed, air-pack breathing apparatus should be donned before proceeding. At higher concentrations a full-body protective Self-Contained Atmospheric Protection Ensemble suit, preferably one made from fluoropolymers, is required.

8.2 Maximum Allowable Fluorine Concentrations

The maximum allowable concentration of fluorine at the place of employment has been established by various organizations and may differ from one country to another. The maximum allowable concentration for gases and vapors is usually given in units of “parts per million = ppm,” that is, parts per million by volume, not by weight. Occasionally, one finds maximum allowable concentrations given in other units, such as mg/m^3 . These units are mostly used for dusts and aerosols, but occasionally they are used for gases as well. The advantage of ppm by volume is that this value is independent of the ambient temperature, whereas the mg/m^3 value varies with temperature. The density of fluorine gas has been known to convert one value to the other. The density of fluorine gas at 101 kPa and 273 K is 1.696 g/L; thus, 1.0 ppm by volume corresponds to $1.696 \text{ mg}/\text{m}^3$ at 101 kPa and 273 K.

Maximum allowable concentration values are often listed in comparison to lethal concentration LC50 or lethal dose LD50. The lethal concentration LC50 is the concentration at which 50% of the test animals die within a specified post-exposure observation period as the result of a controlled exposure to the toxic gas for a certain time. One must check the original data for animal tests to see if this was a whole-body exposure or if the hazardous atmosphere was delivered by a breathing mask. Most of the animal tests are conducted with whole-body exposure. For other paths of administration (injection, intubation, ingestion), the lethal dose is often given in relation to the body weight of the animal. The maximum tolerable concentrations for elemental difluorine established by government agencies are closely tied to the limits for HF.

Table 44 is a summary of maximum allowable concentrations of fluorine in air under different conditions and for different populations. Table 45 gives the full-text

meaning of some of the commonly used abbreviations (“alphabet soup”). This table applies not only to fluorine, but to toxicity of all other chemicals in this encyclopedia. This table used to be at the beginning of *Encyclopedia of Oxidizers* before the chapters were rearranged in alphabetical order.

Table 44: Maximum allowable concentrations of fluorine in air.

CAS number	7782-41-4
NIOSH REL	0.1 ppm (0.2 mg/m ³) TWA
OSHA PEL	0.1 ppm (0.2 mg/m ³) TWA
1989 OSHA PEL	Same as current PEL
1993–1994 ACGIH TLV	1 ppm (1.6 mg/m ³) TWA, 2 ppm (3.1 mg/m ³) STEL
Immediately Dangerous to Life or Health (IDLH) Concentrations	
Original (SCP) IDLH ^a	25 ppm
Existing short-term exposure guidelines: National Research Council 1984	
10-min EEGL	15 ppm
30-min EEGL	10 ppm
60-min EEGL	7.5 ppm

Data source: NIOSH <http://www.cdc.gov/niosh/idlh/7782414.html> as of May 1994

^a Basis for original (SCP) IDLH: The chosen IDLH is based on the statement by [498] that “2 men were able to tolerate 25 ppm very briefly but both developed sore throats and chest pains lasting 6 hours; 50 ppm could not be tolerated.”

Table 45: Abbreviations for IDLH documentation.

ACGIH	American Conference of Governmental Industrial Hygienists
EEGL	Emergency Exposure Guidance Level (NRC)
IDLH	Immediately Dangerous to Life or Health concentration value
LC50	Lethal concentration causing death in 50%
LCLo	Lowest lethal concentration causing death
NIOSH	National Institute for Occupational Safety and Health
NRC	National Research Council
OSHA	Occupational Safety and Health Administration
PEL	Permissible Exposure Limit (OSHA)
REL	Recommended Exposure Limit (NIOSH)

SPEGL	Short-term Public Emergency Guidance Level (NRC)
STEL	Short-term Exposure Limit
TLV	Threshold Limit Value (ACGIH)
TWA	Time-Weighted Average

Data source: NIOSH <http://www.cdc.gov/niosh/idlh/7782414.html>

Based on a review of literature data, the following exposure limits were recommended in 1970 [495]: Emergency Exposure Limit (EEL): 25.0 ppm for 5 min, Emergency Tolerance Limits (ETLs): 15.0 ppm for 10 min and TLV = 1.0 ppm for 8 h.

Short-term public emergency guidance levels (SPEGLs) for fluorine and other hazardous chemicals were established by Committee on Toxicology, Board on Toxicology and Environmental Health Hazards, Commission on Life Sciences, National Research Council [499]. This document contains a very good summary on fluorine toxicity. A similar document is available from the same publisher for chlorine trifluoride. Exposure limits for fluorine are closely related to exposure limits for HF [500]. Different guidelines may apply for emergency short-term limits for military personnel [501].

8.3 Animal Inhalation Toxicity Exposure Test Results

8.3.1 Acute Toxicity Data

Rats, mice, guinea pigs, rabbits, and dogs were exposed to fluorine for 5, 15, 30, or 60 min. [502, 503]. The LC50s and effects at lower concentrations are summarized in Table 46.

Table 46: Lethal concentration data for animal exposures to fluorine.

Species	LC50 (ppm)	Time	Adjusted 0.5-h LC (CF)	Derived value
Rat	185	1 h	231 ppm (1.25)	23 ppm
Mouse	150	1 h	188 ppm (1.25)	19 ppm
Rabbit	270	30 min	270 ppm (1.0)	27 ppm
Guinea pig	170	1 h	213 ppm (1.25)	21 ppm

Data source: [502]

High concentrations of fluorine caused marked irritation of the eyes and respiratory tract, and damage to the lungs, liver, and kidneys. Exposure at or below 100 ppm for 5 min, 70 ppm for 15 min, 55 ppm for 30 min, or 45 ppm for 60 min caused no apparent effects in the animals. The most pronounced effects of the F₂ exposures observed were irritation of the eyes and respiratory tract. Dyspnea was also observed frequently. Although kidney and liver effects were observed, they occurred only at exposures greater than those producing diffuse congestion of the lung. In rats, mice, guinea pigs, and rabbits, effects observed after exposures at approximately 50% and 25% of the LC50 values were not observed at approximately 12.5% of the LC50 values. The ranges of maximal no-observed-effect concentration for the four species are summarized in Table 47.

Table 47: Ranges of maximal no-observed-effect concentrations in animals.

Duration, min	No-observed-effect concentration, ppm	ppm × min product
5	51–88	260–440
15	49–70	740–1100
30	32–35	960–1100
60	28–38	1500–2300

Data source: [502]

8.3.2 Short-Term Exposure

The effects of intermittent exposure to F₂ were studied by exposing mice, rats, and rabbits four times at weekly intervals for 5, 15, 30, or 60 min at repeat intervals ranging from 24 h to 1 week [504]. Lung damage was the most sensitive index of an adverse effect. Animals were sacrificed immediately after the last exposure, or at 7, 14, 21, or 45 days after the last exposure. Two magnitudes of exposure were used: one that caused slight effects after a single exposure and one that produced marked effects after such an exposure. The results of these studies are summarized in Table 48.

Table 48: Pathology in rodents after single and repeated exposures to fluorine.

Species (Strain) ^a	Time, min	Concentration, ppm	Repeated exposures ^b			Single exposure		
			Lung	Kidney	Liver	Lung	Kidney	Liver
Mouse/Swiss-Webster	5	130	1	N	N	1	P	N
Mouse/Swiss-Webster	5	321	1	P	N	3	P	P
Mouse/Swiss-Webster	30	64	1	N	N	1	P	N
Mouse/Swiss-Webster	30	55	1	N	N	1	P	N
Rat (Osborne Mendel)	5	150	1	N	N	1	P	N
Rat (Osborne Mendel)	5	325	1–2	N	N	3	P	P
Rat (Osborne Mendel)	30	68	1	N	N	1	P	N
Rat (Osborne Mendel)	60	75	1–2	N	N	1	P	N
Rat (Osborne Mendel)	60	140	2–3	N	N	4	P	P
Rabbits (New Zealand)	15	56–73	N	N	N	N	N	N
Rabbits (New Zealand)	30	49–55	N	N	N	N	N	N

Data source: [504]

N = normal or no change; P = some pathology; 1, 2, 3, 4 = degree of gross lung pathological change (1 mildest and 4 most severe).

^a 10 mice or rats per group; number of rabbits per group unspecified.

^b Four exposures at weekly intervals.

It was concluded that four weekly exposures to F₂ caused no more, and in some cases, less, damage than a single exposure at the same concentration. The data suggested the development of a tolerance to F₂ inhalation. It was also shown that the LC50 value for

mice was increased by pre-exposing the test animals to F_2 . This provided additional evidence of the development of tolerance. After four exposures (at weekly intervals) to the same concentration, the lungs had slight changes (grade 1). Livers were normal. Kidneys showed slight changes at 7 and 14 days, but were normal at 21 and 45 days. Four repeated exposures, at concentrations that caused no effect after a single exposure, caused no effect either. Four exposures to fluorine caused no more damage than a single exposure to the same concentration. Repeated exposures were made with different concentrations during each exposure. A low, apparently harmless, level was used first. Then, 4, 24, and 96 h later, the LC50 of fluorine was determined. The LC50s of pre-exposed animals were higher and there was less damage to the lungs than in control animals. Exposures to a low concentration were also repeated every third day (four times). At 1, 3, and 7 days after the last exposure the LC50s were determined. Even at 7 days the pre-exposed animals had higher LC50s and showed less edema in the lungs than animals that were not pretreated by previous exposure to fluorine.

Some of the early fluorine toxicity test results obtained as part of the Manhattan project were published only in internal reports that are difficult to obtain, even after declassification [505, 506].

The lethal effect resulting from the inhalation of air containing relatively high concentrations of fluorine was studied in four animal species: 8 rabbits, 20 guinea pigs, 45 to 50 rats, and 45 to 50 mice were each exposed to concentrations of fluorine approximating 100, 200, 500, 1000, and 10000 ppm, respectively [507]. The duration of exposure ranged from 7 h at 100 ppm to 5 min at 10000 ppm. At a concentration of 10000 ppm all animals died during the 5-min exposure period, with the exception of 1 rabbit, which died within 24 h after exposure. All animals exposed at 1000 and 500 ppm were dead within 6 days after exposure. All animals exposed at 200 ppm, with the exception of 2 guinea pigs, were dead within 14 days after exposure. The 7-h exposure at 100 ppm resulted in the death of 7 of the 8 rabbits, 27 of the 50 rats, and 43 of the 45 mice within 14 days after exposure. No deaths occurred among the guinea pigs exposed at this level. All surviving animals were sacrificed during the 3rd post-exposure week. Death in all cases was apparently caused by respiratory failure resulting from acute pulmonary damage. The animals that survived a 2-week post-exposure period either escaped this damage or were able to withstand its effects until resolution had occurred. Damage to internal organs other than the lung was minor or negligible.

The next test series involved lower fluorine concentrations. The toxic effects arising from the daily inhalation of gaseous fluorine were studied in six animal species: 5 dogs, 30 rabbits, 38 guinea pigs, 46 rats, 50 mice, and 30 hamsters were exposed 6 days a week to a concentration of fluorine approximating 8 mg/m^3 (5 ppm) [508]. The animals were exposed for a total of 160 h apportioned over 29 exposure-days, with the exception of the hamsters, which were exposed for a total of 136 h apportioned over 25 exposure-days. Ten of the rabbits and 12 of the guinea pigs were subjected to head exposure, rather than to the complete body exposure to which the majority of the animals were subjected. Toxicity was evaluated from the study of several independent

factors: mortality, body weight response, changes in cellular elements of the blood, and tissue damage. The inhalation of fluorine produced 100% mortality in dogs after 45 h of exposure, and in fully exposed rabbits after 110 h of exposure. At the termination of the experiment, after 160 h of exposure, 90% of the head-exposed rabbits, 27% of the fully exposed guinea pigs, 20% of the mice, 17% of the head-exposed guinea pigs, and 11% of the rats had died. The hamsters, exposed for the last 136 h of the experiment, miraculously survived.

The next animal exposure test series was run at concentrations that were close to the 8 h/day, 40 h/week recommended TLV for humans in a work environment. Groups consisting of 5 dogs, 30 rabbits, 24 guinea pigs, and 18 rats were exposed for 6 days weekly to a concentration of fluorine approximating 0.8 mg/m^3 (0.5 ppm) [509]. Twelve of the rabbits and 12 of the guinea pigs were subjected to head exposure only. Toxicity was evaluated from the study of several factors: mortality, growth response, and histopathological, hematological, and clinical–chemical changes. No mortality resulting from exposure to fluorine at this concentration was observed. Growth was not noticeably affected by exposure, nor were any significant histopathological or hematological changes produced. Blood calcium and NPN levels of the dog and rabbit remained within normal limits. The excretions of urinary fluorine and amino nitrogen by the rabbit were not significantly altered.

8.4 Human Volunteer Inhalation Tests

It has been reported that two men were able to tolerate 25 ppm very briefly but both developed sore throats and chest pains that lasted 6 h; 50 ppm could not be tolerated [498]. Volunteers tolerated 10 ppm for 15 min with minimal irritation. Toxicity data on short-term animal exposures were compiled, normalized, and correlated with human data [495]. Intermittent exposures to 10 ppm were repeated every 3 to 5 min for 15 min over 2 to 3 h with only slight irritation of the eyes and skin noted. Much irritation of the eyes has been noted at 100 ppm, but with no after effects after only 30 s. It has been observed that exposures up to 30 ppm for 5 to 30 min had no ill effects [510]. Exposure to 1 ppm for 1 h is not expected to cause injury.

At NASA Lewis Research Center, 9 male volunteers were observed during and after exposure to F_2 under controlled conditions [511]. Most of the subjects reported that 15–25 ppm fluorine in air caused some nasal and eye irritation after only two or three breaths. All subjects tolerated repeated short-term (duration unspecified) exposures at up to 10 ppm without discomfort.

Five volunteers (aged 19–50) were exposed to F_2 under a variety of conditions that permitted accurate measurement of F_2 concentrations [502]. Exposure took place under a mask that covered the eyes and nose, but not the mouth. Thus, the effects of F_2 on respiration were not routinely measured (some subjects did inhale and some

Table 49: Irritation caused by fluorine in volunteer human subjects.

Concentration, ppm	Time, min	Effects
10	3	No irritation of eyes and nose
10	5	No irritation of eyes and nose; not uncomfortable
10	15	No irritation of eyes and nose, inhaled without irritation of respiratory tract
23	5	Slight irritation to eyes; could inhale without respiratory difficulty (inhaled intermittently over the 5-min period)
50	3	Irritation of the eyes; slight irritation of the nose
67	1	Irritation of eyes and nose; although exposure was quite irritating, concentration not unbearable
78	1	Irritation of the eyes and nose; (less irritating to eyes than cigarette smoke); face slightly irritated after exposure; inhalation caused coughing
100	1	Very irritating to eyes and nose; eyes burned after exposure; felt like "film" over the eyes after exposure; skin felt sticky and slightly irritated after exposure; subjects did not inhale
100	0.5	Very irritating to eyes and nose; no after-effect

Data source: [502]

data on respiratory effects were obtained). The results of this study are summarized in Table 49.

The authors also noted that, when exposure was repeated weekly, the subjects did not perceive as much irritation as they had on first exposure. The apparent development of tolerance is consistent with that seen in experimental animals. Finally, the authors studied the effects of exposure at 10 ppm for 3–5 min every 15 min for 2 or 3 h. All subjects tolerated such repeated exposures with only slight irritation of the eyes and skin. There was marked irritation of the eyes and nose at 100 ppm.

In 1953, the American Conference of Governmental Industrial Hygienists lowered the recommended threshold of exposure for fluorine from 0.7 ppm, a value that had been based on animal-experiment data, to 0.1 ppm. An experience of 9 years at Union Carbide in Oak Ridge, TN, with personnel working in fluorine concentrations several times the newly recommended threshold led safety managers to believe firmly that concentrations up to at least 1.0 ppm were safe [510]. Subsequently, approval was requested from the US Atomic Energy Commission (AEC) to continue using this limit; with US AEC concurrence, the higher limit was tolerated. The health of workers exposed to higher values than 0.1 ppm as recorded over a 4-year period at the medical department of this plant was correlated with measured fluorine concentrations in the air at the work place. The average fluorine values in air at the fluorine generation unit were compiled for the years 1952–1959 inclusive (Table 50). The air samples were the average of 30-min samples collected at a rate of 1 cu ft/min in giant impingers containing 100 mL of 0.5% sodium hydroxide solution. The fluorine content of the solution

was then determined by the Eriochrome Cyanine R method. Reliable techniques for differentiating between fluorine and HF in air were not available. Sixty-one employees were determined to have been present in the fluorine-contaminated environment for a significant portion of their working time. The group included: (1) Individuals who normally spent 50–60% of their daily work time for periods of 7–9 months in the area, and (2) individuals (repair men) who spent as little as 10% of their daily work time in the area but who did this almost continuously and who, because of the nature of their work, had been present when fluorine concentrations were highest. As the gaseous diffusion process for separating the isotopes of uranium uses the salt, uranium hexafluoride, and involves the use of other fluorides such as HF, these employees were potentially exposed to several fluorides.

Table 50: Historical summary of fluorine concentrations in workroom air at a fluorine generation unit.

Year	Number of samples	Fluorine, ppm			Number of samples at or above 1 ppm
		Average	High	Low	
1952	78	1.4	6.6	0.0	47
1953	70	1.1	10.0	0.1	23
1954	51	0.6	7.4	0.0	9
1955	86	1.0	24.7	0.1	23
1956	80	0.9	6.1	0.1	22
1957	126	0.3	3.8	0.1	4
1958	115	0.5	16.6	<0.1	9
1959	120	1.2	11.5	<0.1	29

Data source: [510]

The toxicity of fluorine is closely related to that of HF. The Canadian Atomic Energy Control Board commissioned an update of a 1984 review on the acute toxicity of HF [512]. The study placed particular emphasis on the effects of inhalation of gaseous HF and was divided into two main parts: a literature review and a lethal concentration estimation. The literature review summarized data under four categories: animal studies, controlled human studies, community exposure, and industrial exposure. Data in these areas were critically reviewed for their relevance to lethal concentrations at LC_{LO} , LC_{10} , and LC_{50} levels that were derived in the 1984 report. In the 10 years prior to 1995, only one additional relevant animal study had been published. No new controlled human studies were found, but one community exposure incident was reported. Three new industrial/accidental exposures had been reported since 1984. Evaluation of new data did not change the lethal concentration estimates made in the 1984 report, but revealed the lack of appropriate models to estimate the lethality of irritant and corrosive gases. Additional information on fluorine toxicity can be found in [513, 514].

8.5 Skin Effects of Fluorine Exposure

Heat release from fluorine exposure to unprotected skin can be felt on the exposed skin of the body (up the sleeve, back of the neck, etc.), which begins to feel warm at concentrations of 90 to 240 ppm. At the same time, the exposed hair on the head and arms feels sticky. If this concentration is observed during maintenance operations, or if monitoring instrumentation indicates fluorine or HF in excess of 90 to 240 ppm, personnel should evacuate the area immediately, and remain clear until the concentration is reduced to a safe level (by natural dissipation or by operation of exhaust systems in enclosed areas). Personnel accidentally exposed to these concentrations (100 to 200 ppm) for more than a few minutes experience minor skin irritation, itching, and subsequently a sunburn effect. To limit this after effect, exposed personnel should immediately flush exposed skin areas with water.

8.6 First Aid in Case of Injury by Fluorine or HF

If a person is accidentally exposed to fluorine, the affected parts of the body should be rinsed thoroughly with water as quickly as possible. Fluorine chemical burns on the skin are similar to HF chemical burns and exposed persons should seek medical care as quickly as possible. First aid treatment for F_2 burns on the skin would be similar to first aid treatment for HF burns. The physician in charge of attending to rocket or laser test site personnel should familiarize him/herself beforehand on how to treat F_2 and HF injuries.

Small injuries can be treated with Calcium Gluconate 2.5% Topical Gel, which is available from various pharmaceutical suppliers or can be mixed as needed from calcium gluconate powder and a water-soluble lubricant [515].

The subcutaneous injection of 5% calcium gluconate solution in the perimeter of HF injuries has been recommended repeatedly. The action principle of this treatment is the precipitation and immobilization of fluoride ion as insoluble calcium fluoride. This may be very painful, but at least it prevents the tissue from becoming necrotic. It has been recommended to bath fresh HF injuries in buttermilk (calcium-rich) if no other first aid treatment is available and until the victim can be transported to medical care. There are several reports in the literature describing fatal accidents caused by splashes of hydrofluoric acid on the skin [516–518]. The rapid depletion of calcium was identified as a major cause of death. Eye injuries should be thoroughly rinsed with water, followed by rinses with dilute boric acid solutions to prevent infection. In all cases the victim needs to be quickly transported to a physician. The literature on the treatment of HF injuries is extensive, though occasionally confusing and often contradictory, with no coherent management policy emerging [519, 520].

The hands are the first place where splash injuries caused by fluorine or hydrofluoric acid are likely to occur [521].

Accidental inhalation of fluorine causes severe damage to the lung tissue. First aid treatment is breathing of oxygen, but not forced ventilation. The inhalation of an aerosol from a calcium acetate solution or 2.5% calcium gluconate in normal saline using a nebulizer has been recommended to treat F_2 or HF inhalation injuries.

Additional information on first aid in cases of accidents with fluorine or HF is contained in [44, 522, 523].

8.7 Environmental Effects of Fluorine or HF

Some living green plants have the ability to accumulate fluoride and/or fluorinated organic compounds in their tissue, in particular in areas downwind of aluminum smelters or phosphate ore processing plants. Livestock grazing on meadows where these plants grow has suffered fluorosis poisoning. All necessary steps have been taken to avoid similar problems in the vicinity of rocket or laser test sites or nuclear fuel processing factories [524, 525].

Although the plan to launch FLOX-powered rockets from Cape Canaveral in Florida never materialized, the concern about the potential impact of HF exhaust on the environment surrounding the launch site arose quickly, as soon as such plans were announced in 1963, and had to be addressed in environmental impact statements [526–528].

9 Mixtures of Fluorine with Other Oxidizers

Mixtures of fluorine with other oxidizers can have certain advantages over pure fluorine and pure oxidizers by themselves. Most of all, this statement applies to mixtures of liquid fluorine with liquid oxygen. The common abbreviation for this mixture is FLOX. This cryogenic oxidizer has been tested as a rocket propellant in combination with many different fuels.

9.1 Fluorine/Oxygen Mixtures

Liquid fluorine is miscible with liquid oxygen over the entire range of compositions [529].

9.1.1 Physical Properties of Fluorine/Oxygen Mixtures

The physical properties of FLOX have been investigated over a wide range of compositions [530–532].

The boiling points of the two cryogenic liquids are very similar. A good summary of the physical properties of FLOX mixtures is provided in a NASA publication [10]. Most of the physical properties of FLOX are readily interpolated from those of the two constituents, assuming additive behavior of the physical properties [533].

The boiling point/composition diagram for FLOX mixtures is shown in Figure 23. A 50 mass-% FLOX mixture boils at approximately 87.42K and the fluorine content of boiloff gas is approximately 63.7 mass-%. The curves were calculated from Raoult's law.

Figure 23: Boiling point/composition diagram for FLOX mixtures. (Reproduced and modified from [10].)

The vapor pressure of a 50% F_2 FLOX mixture is shown in Figure 24, where it was interpolated between the curves for LOX and LF_2 (also shown). The densities of three different FLOX mixtures as a function of temperature are shown in Figure 25. The FLOX density curves fall between those for LOX and LF_2 . The viscosity of a 50% F_2 FLOX mixture as a function of temperature is shown in Figure 26.

Figure 24: Vapor pressure of a liquid fluorine–liquid oxygen mixture. (Reproduced and modified from [10].)

Figure 25: Density of three liquid fluorine–liquid oxygen mixtures. (Reproduced and modified from [10].)

Figure 26: Viscosity of a liquid fluorine–liquid oxygen mixture. (Reproduced and modified from [10].)

9.1.2 Chemistry of Fluorine/Oxygen Mixtures

As long as fluorine and oxygen in FLOX are kept at cryogenic temperatures, one would not expect any reactions to take place between the two oxidizers. It is known that if the gaseous oxygen/fluorine mixtures are subjected to a glow discharge or UV irradiation, then various oxygen fluorides can be formed.

The radiolysis of FLOX under the influence of γ -radiation from a ^{60}Co source did not produce any changes in the cryogenic fluid [534].

9.1.2.1 Analysis of Fluorine/Oxygen Mixtures

The fluorine content of F_2/O_2 gas mixtures can be determined in a 10-cm path length Teflon-coated stainless steel cell with sapphire windows by measuring the direct absorption spectrum of F_2 at 278 nm [535].

Oxygen/fluorine gas mixtures can be analyzed by admitting the mixture to a tightly closed gas vial attached to a pressure gauge, adding mercury metal, allowing the reaction of mercury with fluorine to proceed to completion, and measuring the drop in pressure because the fluorine in the mixture has been consumed [536].

9.1.3 Materials Compatibility with Fluorine/Oxygen Mixtures

The purpose of a series of tests was to investigate the feasibility of using fluorine–oxygen mixtures in rocket-propulsion systems containing some non-metallic materials [372]. The tests were divided into two major areas, static tests and dynamic tests. In the static tests, a number of test samples were exposed to various FLOX mixtures, both gaseous and liquid, at atmospheric pressure and virtually static conditions in order to obtain information on compatibility solely as a function of fluorine concentration. The reactivity of the materials tested with FLOX under static conditions is a function of the concentration of fluorine in the mixture.

In the dynamic tests, selected materials were exposed to fluorine and FLOX at various combinations of concentration and flow velocity. Reactivity profiles were generated for these materials as functions of these two parameters (Figure 27).

Figure 27: Compatibility profile of elastomers in FLOX. (Reproduced and modified from [372].)

These graphs show the areas of compatibility and non-compatibility of selected materials in a dynamic fluorine or FLOX environment. At any given fluorine concentration, flow velocity was a strongly significant parameter in the reactivity of FLOX with all materials tested. The ferocity of the reactions ranged from smooth burning to explosive burning. Generally, the fluorocarbon polymers, particularly the fully fluorinated, straight-chain polymers, were most compatible with fluorine and with FLOX. In both static and dynamic FLOX tests, a comparison between cryogenic liquid (77 K = -320 °F) and ambient temperature gaseous (271 to 293 K = 30 to 70 °F) test results indicated that the liquid was more reactive at pressures up to 2850 kPa = 400 psig.

9.1.4 Handling of Fluorine/Oxygen Mixtures

The following publications provide information on the handling of FLOX at rocket test sites and the potential benefits of using FLOX instead of LOX. At one time it was planned to convert the ATLAS launch vehicle from LOX to FLOX. This could not be done without a complete re-evaluation of the compatibility of tankage and component materials with the more corrosive oxidizer, even if the pre-launch exposure duration is only a matter of hours [346].

9.1.5 Selection of FLOX Storage Sites

Siting considerations for the selection of FLOX storage sites and FLOX rocket motor test firing facilities include worst-case “what if” scenarios. One US Government contractor sought approval for the siting of facilities for storing 450 kg (1000 lb_m) of liquid fluorine and for the test firing of motors using 1500 kg (3300 lb_m) of FLOX containing 30% fluorine. Recommendations made by the Space Systems Division of the US Air Force were documented, along with the contractor’s rebuttal [537]. Another contractor requested approval for the siting of a FLOX facility extension involving the installation of 378 and 1900 L (100- and 500-gallon) liquid fluorine tanks.

9.1.6 Consequences of Accidental FLOX Leaks and Spills

The consequences of accidental FLOX leaks and spills are not much different from those of fluorine itself. The same precautions must be taken regardless of whether the transported oxidizer is 100% fluorine or 50% FLOX.

The use of liquid FLOX as an oxidizer in a rocket launch or test facility requires knowledge of the reaction characteristics of these liquids in the event of spillage. The hypergolicity of cryogenic FLOX when spilled in an unconfined manner onto various common materials is of particular interest. In addition, the relative hypergolicity of FLOX in comparison to fluorine was uncertain under these spill conditions. An investigation was therefore undertaken to determine the results of such spillages onto various materials. Small quantities (2.2 to 4.5 kg = 5 to 10 lb) of liquid (FLOX, fluorine or oxygen) were spilled from a height of about 51 cm (20 in) upon several common materials that might be found or placed around a test or launch facility [452]. The materials were confined in stainless steel pans ($0.9 \times 0.9 \times 0.3 \text{ m} = 3 \times 3 \times 1 \text{ ft}$). When liquid fluorine was spilled upon JP-4, smooth burning occurred, as opposed to the multiple microexplosions with FLOX (see below). Because of NASA’s historical interest in 30% FLOX (fluorine-oxygen mixture containing 30 mass-% F₂), the majority of spills were made at this concentration. In a spill of FLOX and JP-4, several rapid machine gun-like microexplosions occurred over a period of 1 to 2 s and then a large fireball formed and expanded to 9 m (30 ft) in diameter. FLOX spilled onto water or into a water spray did not start a combustion reaction. When FLOX was spilled onto charcoal, a smooth, large, brilliant flame developed within a few seconds. From these spill tests, information was obtained in the following areas: **(1)** The hypergolicity of FLOX with various materials upon which it might be spilled, including the effect of oxygen as a diluent on hypergolicity; **(2)** qualitative information on reaction characteristics and combustion propagation by visual observation and high-speed photography; **(3)** visual, photographic, and cinematographic information on the path of the resultant gas clouds.

In preparation for the eventual use of FLOX in launch vehicles to be launched from NASA Kennedy Space Center, the meteorology of launch sites on Merritt Island was examined as to the probable path taken by clouds of spilled FLOX propellant or the exhaust plume of a FLOX/RP-1 rocket [459].

9.2 Fluorine/Ozone Mixtures

As will be discussed in detail in a later chapter on ozone properties, the explosion hazards of liquid ozone can be reduced by dilution with liquid fluorine. Liquid fluorine is the ideal diluent for ozone because it increases instead of decreases the specific impulse when this oxidizer is used in combinations with hydrocarbon fuels.

Liquid fluorine and liquid ozone are totally miscible over the entire range of compositions at 74 to 79 K [529, 538]. This is in contrast to oxygen and ozone, which are not totally miscible and have a miscibility gap. In addition to the binary system F_2/O_3 investigations into the ternary system $F_2/O_3/O_2$ were undertaken. As illustrated by Figure 23 in *Encyclopedia of Oxidizers*, chapter “Ozone,” the homogeneous liquid phase range of LOX/LOZ at 77.4 K is widened by the addition of LF_2 . Mixtures containing 14% O_3 , 72% O_2 , and 14% F_2 are a homogeneous liquid, whereas 20% O_3 and 80% O_2 separate into two phases. The physical properties of F_2/O_3 mixtures are summarized in Table 51.

Table 51: Density of fluorine/ozone mixtures.

Temperature		Ozone concentration, mass-%	Density, g/cm ³	
K	°C		Measured	Calculated ^a
90	−183	0	1.472	1.470
90	−183	31.0	1.499	1.502
90	−183	84.6	1.557	1.556
90	−183	100.0	1.571	1.571
77.35	−195.8	0	1.561	1.561
77.35	−195.8	23.0	1.573	1.573
77.35	−195.8	61.8	1.595	1.594
77.35	−195.8	100.0	1.614	1.615

Data source: [539–541]

^a Calculated from Eqs. 1 and 2:

$$\rho \text{ at } 90 \text{ K} = -183^\circ\text{C} = 0.1009 (\text{mass-fraction } O_3) + 1.4704 \quad (1)$$

$$\rho \text{ at } 77.35 \text{ K} = -195.8^\circ\text{C} = 0.0534 (\text{mass-fraction } O_3) + 1.5611 \quad (2)$$

The density of liquid F_2/O_3 mixtures is a linear function of the ozone content. There is no volume contraction during the mixing.

If one plots the logarithm of viscosity against the ozone concentration in mol-%, one obtains a linear curve that facilitates interpolation for in-between concentrations. Liquid ozone at 90 K is ten times as viscous as liquid fluorine. The lowering of viscosity of liquid ozone by the addition of liquid fluorine is very desirable (Table 52).

Table 52: Viscosity of liquid ozone–fluorine mixtures.

Ozone concentration, mol-%	Viscosity, cPs	
	at 90 K = –183 °C	at 77.35 K = –195.8 °C
100	1.55 ± 0.01	4.15 ± 0.04
79.1	0.905 ± 0.01	—
70.5	—	1.95 ± 0.01
30.5	0.343 ± 0.03	—
26.8	—	0.682 ± 0.02
0.0	0.208 ± 0.01	0.344 ± 0.01

Data source: [540]

The surface tension of liquid ozone is three times higher than that of liquid fluorine (Table 53).

Table 53: Surface tension of liquid ozone–fluorine mixtures.

Ozone concentration, mol-%	Surface tension			
	at 90 K = –183 °C		at 77.35 K = –195.8 °C	
	dyn/cm	N/m	dyn/cm	N/m
100.0	39.9	0.0399	43.55	0.04355
79.1	30.2	0.0302	—	—
70.5	—	—	35.6	0.0356
30.5	19.1	0.0191	—	—
26.8	—	—	22.4	0.0224
0.0	12.3	0.0123	15.5	0.0155

Conversion: 10^5 dyn = 1 N; 1 cm = 10^{-2} m; 1 dyn/cm = 10^{-5} N/cm = 10^{-3} N/m

Data source: [540]

If fluorine/ozone mixtures are evaporated, a reaction between fluorine and ozone begins in the vapor phase. The results are influenced by the temperature of the reactants and the absence or intensity of UV radiation.

It has been proposed that the thermal reaction is not one between fluorine and ozone, but a chain reaction between fluorine and ozone decomposition products [542, 543]. The chain reaction is quickly quenched by the wall. For the photochemical reaction, the initiation step is the photolysis of F_2 into two F atoms, which then cause decomposition of ozone in a rapidly propagating chain reaction. This is similar to the photochemical reactions of halocarbons in the upper atmosphere on Earth, causing destruction of the ozone layer. The quantum yield at 293 K is 4600. The end products of both reactions are fluorine and oxygen.

9.3 Fluorine/Oxygen Difluoride Mixtures

The binary system F_2/OF_2 exhibited typical eutectic formation with a probable break in the fluorine-rich liquidus curve due to a solid phase transition at 45 K (Figure 28) [544]. The eutectic temperature is estimated to be 43 ± 0.5 K and the eutectic composition point is at 0.59 ± 0.02 mol-fraction fluorine.

Halogen Fluorides

Non-Metallic Fluorides

Besides all the work with elemental fluorine (difluorine) as a rocket propellant discussed in the chapter “Fluorine”, the production and investigation of physical and chemical properties of non-metallic fluorides, all of them gases or liquids, have received intensive study. The advantage of most non-metallic fluorides over elemental fluorine is that they are storable as liquids at room temperature. For the past 70 years, these chemicals have been subjected to rigorous scrutiny with regard to their suitability as rocket propellant oxidizers, but each time the final conclusion drawn was that the gain in performance does not justify the complexity of handling these aggressive and corrosive chemicals [1]. The ultimate in specific impulse with storable propellants is possible with non-metallic fluorides as the oxidizers, coupled with a storable fuel such as hydrazine. In the 1990s the priorities in evaluating rocket propellants shifted away from performance and toward environmental friendliness. This shift was partially caused by insufficient training of propellant handling personnel in the safe handling of hazardous propellants. These propellants can be handled safely, given the right protective equipment and adequate training. Here is a “What if?” question: If one were to imagine a scenario in the near future (not too near future, but inevitable in the distant future) where an asteroid ten to hundred times the size of the Chelyabinsk 15 February 2013 impact were threatening to impact a populated area of Earth and it needed to be diverted on short notice and the only storable rocket propellants capable of providing the necessary specific impulse to reach and divert the wayward asteroid are chlorine pentafluoride and hydrazine, what would your choices be? One would have to see the greater benefit to mankind and neglect the minor environmental impact of using fluorine-based propellants and releasing hydrogen fluoride (HF) into the atmosphere! The main problem in responding to an extraterrestrial threat on short notice would be the readiness of fluorine propellant technology in the US, which has fallen into oblivion since the more competitive days of Sputnik and Star Wars.

At the time when a German book on rocket propellants was published in the 1960s, the area of fluorine and fluorine-based propellants was flourishing and still undergoing active investigation, but in the meantime the interest has waned and the priorities have shifted. Nevertheless, we think it is appropriate to provide here a survey of the physical and chemical properties of non-metallic fluorides and to examine their potential application as rocket propellants. A substantial amount of government funding has gone into developing this technology and the work needs to be documented in a useful format. Some of these non-metal fluorides have also found potential applications as oxidizers in chemical lasers. They can be used as ignition fluid in the form of a hypergolic slug to start up bipropellant rocket engines with non-hypergolic

fuels or solid rocket motors, or to start non-catalytic metalized monopropellant engines (MONEX). All of the non-metal fluorides are capable of forming complex fluoro salts, which are essentially non-metal fluorides in solid form, and open up new applications. They are readily storable and can be made to release the volatile fluoride or elemental fluorine on demand.

Fluorine chemistry as a whole has benefited tremendously from the work done during the Manhattan project in WW-II and following years for the isotope separation using UF_6 . During that time, in addition to UF_6 , many other fluorides, metallic and non-metallic, were synthesized and characterized. The non-metallic fluorides were examined at that time because they may have been unwanted byproducts or they may have been looked at as desirable reactants as substitutes for elemental fluorine in the uranium processing, but with better room-temperature storability.

Many non-metallic fluorides, such as chlorine trifluoride or bromine trifluoride, exhibit the same reactivity that we have come to appreciate and respect (or fear) with elemental fluorine. They ignite hypergolically with most rocket fuels and sometimes, to the surprise of the test stand crew, also with materials of construction. Other non-metallic fluorides have certain advantages over elemental fluorine, such as reduced corrosivity, higher boiling point, or higher density. In spite of this, non-metallic fluorides have not found any flight use as rocket propellants. In some cases, elemental fluorine is needed to produce non-metallic fluorides. Consequently, non-metallic fluorides are more expensive to make than elemental fluorine. Because the exhaust gases from rockets with fluorine and fluorine compounds as oxidizers contain HF, they all share the same environmental problems of toxicity, not only as reactants but also in their exhaust products. If at all, these oxidizers may in the future only be used in upper stages of launch vehicles or in kick stages operating outside the atmosphere. Only the non-metallic fluorides of the lighter elements (oxygen, nitrogen, halogens) are useful as rocket propellants. Fluorides of boron, carbon, or phosphorus are not suitable as rocket propellants. Sulfur hexafluoride is an exception because it is used as an oxidizer in torpedo steam generator propellants. Additional monograph information on non-metallic fluorides (most of them including halogen fluorides, and some of them also including organic fluorine compounds and the infinite number of publications on fluorocarbon polymers) can be found in the publications listed in Table 1. Note that

Table 1: Literature summaries on non-metallic fluorides.

Topic	Author(s)	Year	References
Fluorine and its compounds	Hazeldine and Sharpe	1951	[2]
Fluorine-derived chemicals as liquid propellants	Gall	1957	[3]
Fluorine chemistry and technology	Gall	1959	[4]
Fluorine chemistry	Simons	1950–1964	[5]
Advances in fluorine chemistry	Stacey, Tatlow, and Sharpe	1960–1973	[6]

Table 2 contains a literature summary specifically on halogen fluorides (which would exclude oxygen and nitrogen fluorides).

In addition to monographs on fluorine chemistry, there is a monthly periodical that contains numerous publications on fluorine chemistry, including chemicals that are potentially useful as rocket propellants [7]. A book series *Advances in Fluorine Science* was published in 2006 [8].

There are many comprehensive works on non-metallic fluorides, starting with halogen fluorides, continuing with oxygen and nitrogen fluorides, and many fluoro complex salts. Most of these compounds are potentially useful as oxidizers in rocket propellants.

Three reviews summarized the publications during the period 1955–1967 directed toward the development of energetic oxidizers for use in advanced chemical propellants [9]. The source material for these reviews included over 1200 technical reports and 1150 references. The chapter on inorganic oxidizers included sections on such N-F compounds as NF_3 , N_2F_2 , N_2F_4 , HNF_2 , NF_3O , ClNF_2 , NF ions, NOF , NO_2F , N_3F , and such fluorohalogens as ClF_3 , ClF_5 , ClF ions, ClO_2F , ClO_3F , ClO_3OF , and the fluorides of bromine and iodine; such oxygenated compounds as OF_2 , O_2F_2 , O_3F_2 , NO_2OF , dioxygenyl salts, chlorine oxides, and the perchlorates. A chapter on organic oxygen–fluorine oxidizers described the CFO and CFNO compounds and the fluorinated nitroso, nitro, nitrite, and nitrate compounds.

Because fluorine is a strongly electronegative element and all elements to its left and below in the periodic table of elements are less electronegative, chemical homopolar bonds of fluorine with other non-metals are more or less polarized. Fluorine is always the more electronegative atom in the compound. Going by the chemical convention of naming compounds with the cation first and the anion last, non-metallic fluorides should be named with the central atom first and the fluoride designator last, i.e., oxygen difluoride and not fluorine oxide.

The understanding of the nature of the chemical bond in fluorine compounds was totally revamped when the first noble gas fluorides were detected in the 1960s. In the following decades, a substantial amount of effort was devoted to computational chemistry in an effort to explain the unexpected stability of noble gas fluorides and to predict new, as yet undiscovered fluorides that might also be useful as rocket propellants. Chlorine pentafluoride would be the best example for this type of discovery, but it is the only one that had advanced to the level of actual testing in rocket engines.

The theoretical rocket propellant chemist needs a complete understanding of the bond strength in fluorides and the molecular structure. For instance, the polarity of bonds in fluorides and the symmetry of the molecule determine the physical properties such as freezing points and boiling points.

The following literature on the molecular structure of fluorides [10] and the bond energies of fluorine bonds [11] will be a good starting point for future considerations in the search of even more energetic rocket propellants. The hypervalency of halogen atoms in polyhalogens such as ClF_3 , BrF_5 , IF_7 , ICl_4 , etc., has been described in terms of

sp^3d , sp^3d^2 , or sp^3d^3 hybridization of the valence orbital of the hypervalent atom and the formation of localized electron pair bonds involving hybrid orbitals. The formation of these directed bonds has been argued either from Pauling's principle of maximum overlap or from the "Pauli repulsion" between electrons of the same spin.

In addition to being considered as liquid rocket propellants, many non-metal fluorides have been converted to fluoro-onium cations or fluorometallate salts, which have been evaluated as ingredients for solid rocket propellants and solid gas generants for gaseous difluorine generators from a solid, storable form of fluorine.

Some overly enthusiastic computational chemists claimed that the performance of future more powerful rocket propellants (in particular, oxidizers) can be predicted entirely by quantum mechanical calculations [12]. In spite of advances in computational chemistry, much work remains to be done by chemists in the laboratory. Results of molecular orbital calculations for specific fluorine compounds are discussed in the following sections.

Binary Fluorides

Binary fluorides contain only one element other than fluorine. Fluorides that contain more than one other element are discussed in a later section on ternary fluorides. A literature bibliography dealing specifically with molecular structures and bonding energies in binary fluorides was published in 1976 [13].

The molecular geometries and electronic structures of 14 fluorides were optimized using density functional theory (DFT) and Møller–Plesset perturbation theory methods and an attempt was made to correlate structural and energetic parameters with the acute toxicity (expressed as $-\log LC_{50}$ of fluorides to rats) to establish quantitative structure–activity relationships [14]. The toxic mechanism appears to be controlled mainly by electronic quality factor (the maximum net atomic charge on fluorides). There was some agreement with the experimental values, and the model had good stability and a strong prediction ability.

1 Halogen Fluorides

Halogen fluorides are powerful oxidizers comparable with fluorine itself and ignite hypergolically with many commonly used fuels. They have the advantage over fluorine that they are not cryogenic liquids but can be stored as liquids at room temperature (although some will have substantial vapor pressures). The physical and chemical properties of halogen fluorides have been measured in detail as part of their evaluation as rocket propellants and the most essential data are summarized in this chapter. Halogen fluorides represent a fascinating class of chemical compounds. They generally exhibit amphoteric character and can form complexes with strong Lewis acids and

bases. The central halogen atom in the compounds can have oxidation states ranging from +1 to +7 and coordination numbers from 1 to 8.

Additional summaries on physical and chemical properties of halogen fluorides can be found in references summarized in Table 2 (in chronological order).

Table 2: Literature summary of publications on chemical and physical properties of halogen fluorides.

In addition to summary publications in the open literature, there exists a plethora of contractor reports on government-sponsored work on halogen oxidizers that would fill an entire book by themselves if someone made the effort to gather and catalog this work by the type of chemical investigated and the type of rocket propellant data gathered. Most of these reports deal with more than one fluorine-containing chemical at a time. They may deal with liquid and/or solid fluorine-containing compounds. Several of these reports are listed in this book more than once, each time at the chapter of the specific halogen fluoride or other non-metallic fluoride being investigated and described in the report. Some of the reports on high-energy storable rocket propellants may even include work on fuels (intended to be combined later with storable halogen oxidizers), which would be discussed later in a separate chapter of this book. Table 3 may serve as a starting point for a more detailed search of the contractor reports. Many of the reports are now only of historical interest because it is unlikely that fluorine oxidizers will again be used as rocket propellants as long as concerns about environmental pollution and the accidental exposure of propellant handling person-

nel to toxic chemicals persist. In view of the very limited future military utility of any of these toxic chemicals, the distribution limitations on several of these reports should now be relaxed. There may be some commercial uses, e.g., in organic synthesis or batteries and portable energy sources, which would be a late payback for the substantial sums of taxpayer's money spent on this type of work. Those benefits cannot be realized while the information is still kept under lock and key, simply because nobody has made an effort to have it released.

Table 3: Summary of contractor reports on the synthesis of high-energy oxidizers.

1.1 Physical Properties of Halogen Fluorides

It is interesting to compare the physical properties and thermal stability of halogen fluorides in a table where the column headers are the three core halogens chlorine, bromine, and iodine, and the rows going down list compounds with increasing states of oxidation. Table 4 lists the presently known halogen fluorides, including boiling points and the year of their discovery. As can be seen, all the compounds expected to

exist were synthesized before 1963 and their properties have been summarized previously. The fact that the heptafluoride of chlorine does not exist can be explained by steric arguments (there is just not enough space surrounding the chlorine atom).

Table 4: Known halogen fluoride molecules and their boiling points and year of discovery.

Oxidation State of Central Atom	Chlorine	Bromine	Iodine
+I	ClF −100 °C Ruff (1928)	BrF +20 °C Ruff (1933)	IF Unstable Schmeisser (1960)
+III	ClF ₃ +12 °C Ruff (1930)	BrF ₃ +126 °C Lebeau, Prideaux (1905)	IF ₃ Unstable Schmeisser (1960)
+V	ClF ₅ −140 °C Maya (1962)	BrF ₅ +41 °C Buff (1931)	IF ₅ +98 °C Gore (1871)
+VII			IF ₇ +4.8 °C Ruff (1930)

All of the halogen fluorides listed in Table 4 can be synthesized directly from the elements. Variation of the reaction parameters, such as stoichiometry of the reactants and reaction time and pressure, determine the composition of the product. Many of the prior publications deal with the relatively easy-to-obtain chlorine trifluoride. Bromine and iodine fluorides are less suitable as rocket propellants because the heavy central atom increases the average molecular weight of the exhaust gases and decreases the specific impulse. Iodine has the advantage over chlorine and bromine in that it can form fluorides of heptavalent iodine, containing a higher percentage of fluorine than pentafluorides or trifluorides. The higher fluorine content does not compensate for the disadvantage of the high molecular weight of the exhaust gases, a fact that we try to demonstrate with the data in Table 5.

Table 5: Comparison of fluorine content of halogen fluorides.

	ClF	ClF ₃	ClF ₅	BrF ₃	BrF ₅	IF ₅	IF ₇
Molecular mass, g/mol	54.5	92.5	130.5	137	165	212	260
Fluorine content, mass % F	34.9	61.6	72.8	41.6	51.6	40.1	51.2
Average molecular mass of combustion products with hydrogen as the fuel at the stoichiometric mixture ratio	28.3	24.1	22.7	35.2	28.5	36.3	33.5

Chlorine pentafluoride forms the lowest average molecular mass (22.7) combustion products with hydrogen or other hydrogen-containing fuels of all the halogen fluorides examined here. As far as availability is concerned, chlorine, as the central atom, is much more readily available as a raw material than bromine or iodine. The average molecular weight of combustion products of fuels with chlorine fluorides is lower than that with bromine or iodine fluorides. The reactivity of halogen fluorides with hydrogen-containing fuels can be ranked as follows [20]:

Table 6 is a summary of the physical properties of halogen fluorides.

Table 6: Comparison of physical properties of elemental fluorine, elemental chlorine, and halogen fluorides.

Com- pound	CAS RN	Freezing point			Boiling point			Density, liquid (at __ °C) g/cm ³

1.2 Reactions of Halogen Fluorides

Halogen fluorides have been evaluated as selective fluorinating agents for the synthesis of organic mono- and poly-fluoro-compounds [31]. The reactivities of halogen monofluorides were compared with those of their stoichiometric equivalents. The mechanisms of the reactions of halogen fluorides and their inorganic complexes with organic compounds still need to be identified.

Highly fluorinated organic compounds can be prepared by fluorination with metal fluorides, electrochemical fluorination, fluorination with elemental fluorine or halo-

gen fluorides [32]. From Prozac to Teflon, many of the most important products of the chemical and life-science industries rely on organic fluorine chemistry for their useful properties. The semiconductor industry uses non-metallic gaseous fluorides to clean their vacuum deposition chambers.

Halogen fluorides can serve as non-aqueous solvents for a number of fluorination and salt-forming reactions [30].

All of the halogen fluorides can be handled safely and are not shock sensitive (as opposed to NCl_3 or NI_3).

Although the last halogen fluoride molecule was discovered in 1962, a large number of halogen fluoride ions (anions and cations) have been discovered since then and their structures established. Essentially, all of the possible binary halogen fluoride molecules and ions have now been synthesized and characterized. Owing to the large number of possible oxidation states, coordination numbers and sterically active free valence electron pairs, this family of compounds is of particular interest from a theoretical structural point of view, but also as a source of high-energy oxidizers.

One of the most significant chemical characteristics of halogen fluorides is their amphoteric nature, i.e., their ability to act as a base toward strong Lewis acids and as an acid toward strong bases. These interactions result in the formation of complex fluoro cations and anions respectively, according to:

where X is another halogen (Cl, Br, I) or a metalloid (B, P, As, Sb). This amphoteric nature of halogen fluorides was first recognized by Woolf and Emeleus. As BrF_3 shows a relatively high electric specific conductance of $8 \times 10^{-3} \Omega^{-1} \text{cm}^{-1}$, self-ionization was postulated according to:

Although this assumption is certainly correct for BrF_3 , the specific electric conductances reported for the other halogen fluorides are quite low and often were at the lower limits of the sensitivity of the experimental equipment.

Table 7 summarizes the possibly existing and presently known binary halogen fluoride ions. As can be seen, all ions are known, with the exception of ClF_8^- , ClF_6^- , BrF_8^- , Br_2F^+ , and I_2F^+ .

Table 7: Halogen fluoride ions.

Oxidation state	Cation	Parent molecule	Anion
+1	Cl_2F^+	ClF	ClF_2^-
+3	ClF_2^+	ClF_3	ClF_4^-

+5	(IF_4^+)	IF_5	IF_6^-
+7	(IF_6^+)	IF_7	IF_8^-

Data source: [27]

Note: Compounds listed in {braces} do not exist, those in (parentheses) may exist but have not as yet been prepared.

2 Chlorine Fluorides

Depending on the reaction conditions, the reaction of dichlorine with difluorine can lead to various chlorine fluorides in increasing states of oxidation of the chlorine atom, often in mixtures with each other.

2.1 Chlorine Monofluoride

Under the right conditions, and only under those, a stoichiometric equimolar mixture of chlorine and fluorine reacts to form chlorine monofluoride (chlorine fluoride, ClF, CAS RN [7790-89-8]). The history of the preparation of chlorine monofluoride is remarkable for the number of failed attempts at preparing it. Moissan found no apparent reaction when fluorine and chlorine were mixed at room temperature. Lebeau remarked that one may conclude that fluorine and chlorine react neither directly nor indirectly at room temperature, as fluorine displaced chlorine from chlorides without producing a chlorine fluoride. Lebeau also observed that fluorine dissolved freely in liquid chlorine at 193 K (-80°C), but there was no indication that any definite compound was formed. The solution evolved fluorine when cooled to the freezing point of chlorine. It is unlikely that chlorine fluoride would ever be used as a rocket propellant, as the higher fluorides, chlorine trifluoride, and chlorine pentafluoride have the advantage of better storability and higher fluorine content. Chlorine fluoride is only of interest as an intermediate in the production or decomposition of chlorine trifluo-

ride or chlorine pentafluoride. As an oxidizer in rocket engines, chlorine fluoride does not have any particular advantages as its performance is not any better than that of fluorine or chlorine trifluoride. If one makes storable oxidizers by the fluorination of chlorine, one should continue to do so past the oxidation level of Cl^{1+} and go all the way to trivalent or even pentavalent chlorine.

Unlike BrF and IF , ClF shows little tendency to associate or disproportionate but instead exhibits a partial double bond character.

2.1.1 Preparation of Chlorine Monofluoride

Chlorine monofluoride, ClF , forms in a flame-like reaction from the elements [33–35]. Chlorine trifluoride is formed as a byproduct that is left behind owing to its lower volatility. The maximum computed flame temperature was 1409 K at a mixture containing 48.3% fluorine. This reaction can sometimes proceed with explosive violence and it has flammability limits similar to conventional oxidizer/fuel mixtures [36]. The spontaneous explosion limits, the pressure and temperature conditions dividing the explosion region from the non-explosion region for a gaseous mixture in a closed vessel, were found for mixtures of chlorine and fluorine in the 403–473 K (130–200 °C) temperature range. The results showed that the Semenov thermal explosion theory is applicable to the chlorine–fluorine system. The reaction can also be initiated by ultra-violet light.

The kinetics and thermodynamics of these reactions were investigated in efforts to obtain optimal yields of the desired reaction products [37]. The rate of reaction of chlorine with fluorine to form chlorine fluoride was measured in the temperature range 353–401 K (80–128 °C), and the spontaneous ignition limit of the stoichiometric mixture was studied at pressures ranging from 15 to 280 mm Hg and temperatures ranging from 403 to 443 K (130 to 170 °C). The reaction was first order with respect to fluorine and one half order with respect to chlorine. The activation energy obtained from rate studies was 82.8 kJ/mol (19.8 kcal/mol). Neither argon dilution nor the variation of the surface-to-volume ratio affected the observed kinetics. Incipient decomposition of the products often limits the yield of such reactions. The reversal of the formation kinetics is dependent on the decomposition kinetics of ClF_3 and ClF_5 [38].

Although ClF can be prepared directly from the elements, it is generally preferable to employ the reaction of ClF_3 and Cl_2 according to the equation

This reaction was first reported by Schmitz and Schumacher. Reaction conditions were optimized for temperatures between 393 and 453 K (120 and 180 °C) and pressures between 1.1 and 4.6 MPa (160 and 670 psi) and reaction times between 6 and 65 h. Best results (95% yield) were obtained at 423 K (150 °C), 4.27 MPa (620 psi), and 18 h [39]. A trap cooled to 131 K (–142 °C) was used to retain impurities such as Cl_2 , ClF_3 , and FClO_2 , whereas the ClF was condensed in a trap held at 77 K (–196 °C).

2.1.2 Physical Properties of Chlorine Monofluoride

At 173.1 K (−100 °C) chlorine monofluoride condenses to a yellowish liquid, and at 117.6 K (−155.5 °C) it freezes to a white solid. The vapor pressure of liquid chlorine monofluoride can be calculated from

$$\log_{10} P_v = 15.738 - 3109/T + 153800/T^2$$

where P_v is the vapor pressure in mm Hg and T is the temperature in kelvin. A similar Antoine equation from [40] National Institute of Standards and Technology (NIST) Chemistry WebBook valid for the range from 129.7 to 172.6 K is as follows:

$$\log_{10} P_v = 6.03113 - 983.517/(T - 9.791)$$

where P_v is the vapor pressure in bar and T is the temperature in kelvin. The latter equation was used to construct the vapor pressure chart shown in Figure 1.

Figure 1: Vapor pressure of chlorine monofluoride. (Chart created by Schmidt 2016 based on data from [40].)

Liquid ClF is completely miscible at a molar ratio of 1 : 1 with OF₂ at 125 K, with ClO₃F at 160 K or with C₃F₈ at 160 K, but forms two separate layers with LOX at 90 K, NF₃ at 150 K, H₂F₂ at 173 K, or ClF₃ at 174 K [41].

2.1.3 Thermodynamic Properties of Chlorine Monofluoride

The heat capacity of gaseous chlorine monofluoride as a function of temperature can be expressed by the Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + E/\tau^2$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000: $\tau = \text{K}/1000$, and A, B, C, D, and E are constants listed in Table 8 for two temperature ranges.

Table 8: Thermodynamic property polynomial equation coefficients for chlorine monofluoride gas.

Temperature range, K	298–2300	2300–6000
A	33.00963	400.6418
B	7.780901	–226.2720
C	–4.389142	49.98708
D	0.894945	–3.436085
E	–0.258478	–341.4424
F	–61.31694	–626.3866
G	254.2747	327.8775
H	–50.29210	–50.29210

Data source: [40]

The standard enthalpy of formation of the gas is $\Delta H_f^{298} \text{ gas} = -50.29 \text{ kJ/mol}$. The enthalpy of formation of gaseous chlorine monofluoride as a function of temperature can be expressed by the equation

$$H^\circ - H_{298.15}^\circ = A\tau + B\tau^2/2 + C\tau^3/3 + D\tau^4/4 - E/\tau + F - H$$

where H° is the standard enthalpy in J mol^{-1} , τ is the temperature in kelvin divided by 1000: $\tau = \text{K}/1000$, and A, B, C, D, E, F, and H are constants listed in Tables 2–7 and 8 for two temperature ranges. The standard entropy of gaseous chlorine monofluoride as a function of temperature can be expressed by the equation

$$S^\circ = A \times \ln(\tau) + B\tau + C\tau^2/2 + D\tau^3/3 - E/(2\tau^2) + G$$

where S° is the standard entropy in $\text{J mol}^{-1} \text{K}^{-1}$, τ is the temperature in kelvin divided by 1000: $\tau = \text{K}/1000$, and A, B, C, D, E, and G are constants listed in Tables 2–7 and 8 for two temperature ranges. Thermodynamic functions of ClF at 298.16 K were calculated from spectroscopic data and gave the following results for the free energy function $-(F_0 - H_0)/T = 44.904 \text{ cal mol}^{-1} \text{K}^{-1}$, entropy $S_0 = 52.045 \text{ cal mol}^{-1} \text{K}^{-1}$, and the molar heat capacity $C_p = 7.672 \text{ cal mol}^{-1} \text{K}^{-1}$ [42].

Additional data for thermodynamic properties of ClF are listed in Table 21.

2.1.4 Optical Properties of Chlorine Monofluoride

See Figure 40 in Section 2.3.2.13 “Spectroscopic Data for Chlorine Pentafluoride,” which contains an ultraviolet (UV) absorption spectrum of ClF in comparison with that of other halogen fluorides.

2.1.5 Chemical Properties of Chlorine Monofluoride

Halogen monofluorides can readily be added to C=C double bonds. As the elimination of HF is usually highly exothermic, this type of reaction is often violent and requires careful control of the reaction conditions. With hydroxyl groups the following reactions were observed:

Ultraviolet photolysis of matrix-isolated ClF_3 or a mixture of ClF and F_2 at 16 K resulted in formation of difluorochlorine free radical $\bullet\text{ClF}_2$, which was identified by its infrared (IR) absorption at $\sim 575\text{ cm}^{-1}$ [43, 44]. Much weaker absorptions were observed at 536 and 242 cm^{-1} .

Reactive species often react prematurely in the inlet to a mass spectrometer before a clean mass spectrum can be obtained. Cooling the mass spectrometer inlet will allow the sample to enter the ionization chamber unadulterated. Mass spectra of ClF and several other reactive fluorides were obtained by this method [45]. It will also allow the sample to be examined for dimer association in the vapor phase.

Chlorine fluoride forms the FCl_2^+ cation with strong Lewis acids [46], and the ClF_2^- anion with strong Lewis bases [47, 48].

2.2 Chlorine Trifluoride

Chlorine trifluoride, ClF_3 , CAS RN [7790-91-2], is the most thoroughly studied non-metallic fluoride that was once under evaluation as a rocket propellant. The closest chlorine trifluoride has ever come to being used as a rocket propellant was in the ship-board CONDOR missile under development by the US Navy during the early 1960s, but the program was abandoned in 1967. At room temperature and sea level pressure, ClF_3 is a nearly colorless gas that condenses at $284.9\text{ K} = +11.75^\circ\text{C}$ to form a faintly yellow liquid. In the solid state (below $196\text{ K} = -77^\circ\text{C}$) it is a colorless solid. The odor of ClF_3 is similar to that of fluorine or chlorine and its odor can be detected at very low concentrations in air. There are more reliable instruments than the human nose available for early detection of ClF_3 vapors in the event of a leak.

Chlorine trifluoride was being tested in Germany as early as WW-II as an ignition fluid in flame throwers and rocket engines, but did not find any flight applications at that time. One of the code names for ClF_3 was "N-Stoff." After the war, there were some residual stocks of ClF_3 at Bayer Leverkusen that nobody dared to touch and which were eventually neutralized and disposed of.

In addition to summary reports on non-metal fluorides and halogen fluorides as a group already listed in earlier tables, there are many summary documents specifically on chlorine trifluoride such as those listed in Table 9.

Table 9: Summary reports on chlorine trifluoride.

2.2.1 Production of Chlorine Trifluoride

Ruff and Krug, who prepared ClF_3 for the first time, synthesized this compound by total synthesis directly from the elements by mixing chlorine and fluorine in the appropriate volume ratio at $103\text{ K} = -170^\circ\text{C}$ [54].

For industrial production, the reaction is better carried out at higher temperatures, at $473\text{ K} = 200^\circ\text{C}$ in a copper reaction vessel. The raw product can be refined by fractionated distillation in a copper apparatus. Large quantities of chlorine trifluoride were first produced in Germany during WW-II and were intended as a hypergolic ignition fluid in rocket engines and artillery shells. In the vicinity of Falkenhagen (Mark Brandenburg), IG Farben established an underground production plant that could produce 5 metric tons of ClF_3 /day. A nearby facility was intended for the production of Sarin (a nerve gas). In the course of the war events, the plant was relocated to Stulln (Bavaria) in the vicinity of a fluorspar mine, but did not resume its production before the end of the war [55–57]. The compound was made by heating the proper proportion of the gaseous elements to 553 K (280°C) in a U-shaped tube. The vapors were condensed at 193 K (-80°C) and passed into iron cylinders, which were vented several times to allow unreacted fluorine, chlorine, and chlorine monofluoride to escape and be recycled. Apparently, the German army intended to use chlorine trifluoride in shells against aircraft and tanks because of its incendiary properties.

Chlorine trifluoride does not have any other large-scale industrial applications and only small quantities are produced at this time. In the 1960s the majority of ClF_3 production capacity in the US resided with Allied Chemical.

Besides thermal reaction, ClF and ClF_3 in addition to ClOF_3 can be produced by photochemical reaction of chlorine/fluorine mixtures. The chemical kinetics of the UV photochemical formations of ClF , ClF_3 , and ClF_3O were investigated experimentally to obtain information relating to optimal conditions for the formation of ClF_3 and the reaction mechanisms involved [58, 59]. The photolysis of ClF_3 was also investigated because it limits the yield. At a wavelength of 365 nm , the quantum yield of the reaction

was found to be about 1 and that of the reaction

was found to be considerably less than 1. This proves that these are not chain reactions.

2.2.2 Physical Properties of Chlorine Trifluoride

The physical properties of chlorine trifluoride were summarized in a very useful company product information brochure once compiled by Allied Chemical in the early 1960s that is no longer available, but from which most of the data in Table 10 were copied and verified by data downloaded later from a NIST web site.

Table 10: Physical properties of chlorine trifluoride.

Property	SI Units	MKS Units	Source
Molecular mass	92.448 g/mol	10.8169 mol/kg	[40]
Melting point	196.84 K	-76.32 °C	Allied Chemical
Melting point	196.94 K	-76.21 °C	[41]
Melting point	196.81 K	-76.34 °C	[60]
Boiling point (b.p.)	284.91 K	11.75 °C	Allied Chemical
Boiling point	285.1 K	11.95 °C	[41]
Boiling point	284.9 K	11.75 °C	[60]
Triple point	196.84 K	-76.31 °C	[61]
Critical temperature	426.7 K	153.54 °C	Allied Chemical
Density, liquid at 285 K	1.8480 g cm ⁻³	0.0667 lb/in. ³ at 53 °F	
Vapor pressure at 294.2 K (21.1 °C)	156.5 kPa	21.5 psia	[62]

2.2.2.1 Density of Chlorine Trifluoride

A corrosion-resistant pycnometer was developed to measure the density of liquid ClF₃ and ClF₃ mixtures at various temperatures [63]. The density of liquid chlorine trifluoride under its own vapor pressure between 268 and 319 K (-5 and +46 °C) can be expressed by the following second-order polynomial equation [64]:

$$\rho_t^4 = 1.8853 - 2.942 \times 10^{-3}t - 3.79 \times 10^{-6}t^2$$

where ρ is the density in g/cm³ and t is the temperature in °C. The density calculated from this equation is illustrated in Figure 2. At 273 K = 0 °C the density is 1.8853 g cm⁻³; at boiling point it is 1.8480 g cm⁻³.

Figure 2: Density of liquid chlorine trifluoride. (Graph created by Schmidt 2018, based on data from [64].)

More recent density measurements are illustrated in Figure 3. The data in Figure 3 for temperatures between 251 and 434 K (−22 to +161 °C) can be expressed by a third-order polynomial formula

$$\rho = 4.924 - 2.517 \times 10^{-2} T + 7.38429 \times 10^{-5} T^2 - 8.215 \times 10^{-8} T^3$$

where ρ is the density in g/cm³ and T is the temperature in K.

Figure 3: Density of liquid chlorine trifluoride. (Graph created by Schmidt 2018, based on data from [65].)

2.2.2.2 Velocity of Sound in Chlorine Trifluoride

The velocity of sound in liquid chlorine trifluoride was measured over the pressure range from saturation pressure up to 6.88 MPa (1000 psia) and the data are summarized in Table 11 [66]. The sonic velocity increased slightly with pressure but decreased with temperature.

Table 11: Velocity of sound in liquid chlorine trifluoride.

Temperature		Pressure		Sonic velocity	
K	°C	MPa	psia	m/s	ft/s
259	−14.12	Saturation	Saturation	991.9	3254.3
259	−14.12	3.45	500	1002.6	3289.4
259	−14.12	5.52	800	1010.0	3313.6
259	−14.12	6.89	1000	1013.5	3325.1
277.6	+4.43	Saturation	Saturation	923.1	3028.5
277.6	+4.43	3.45	500	933.5	3062.7
277.6	+4.43	5.52	800	939.2	3081.4
277.6	+4.43	6.89	1000	945.1	3100.7

Data source: [66]

The sonic velocity of saturated liquid ClF_3 as a function of temperature is illustrated in Figure 4.

Figure 4: Sonic velocity of saturated liquid ClF_3 as a function of temperature. (Graph created by Schmidt 2018, based on data from [65].)

The sonic velocity for temperatures between 213.4 and 347.6 K (−59.7 to +74.5 °C) in Figure 4 can be expressed by the following linear equation:

$$c = 1951.8 - 3.7508 T$$

where c is the sonic velocity in m/s and T is the temperature in kelvin.

2.2.2.3 Compressibility Coefficient of Liquid Chlorine Trifluoride

The adiabatic compressibility of liquid chlorine trifluoride was curve fitted from experimental data and expressed by the equation

$$\beta = 6.2594 \times 10^{-3} + 6.1059 \times 10^{-5}t + 3.7345 \times 10^{-7}t^2 + 2.6649 \times 10^{-9}t^3 + 2.1283 \times 10^{-11}t^4$$

where β is the compressibility in atm^{-1} and t is the temperature in °C. The data calculated from this curve-fitted equation are shown in Figure 5.

Figure 5: Adiabatic compressibility of liquid chlorine trifluoride. (Reproduced and modified from [65].)

2.2.2.4 Vapor Pressure of Chlorine Trifluoride

The temperature dependence of vapor pressure was measured in support of uranium isotope separation programs [61, 67]. At 273 K = 0 °C the vapor pressure is 60.1 kPa = 0.595 atm = 8.73 psia. At room temperature (298 K = 77 °F) the vapor pressure is

1292 mm Hg = 172.2 kPa = 1.70 atm = 24.99 psia. The data between 226 and 303 K (−47 to +30 °C) can be represented by the following equation:

$$\log_{10} P_v = 7.36711 - 1096.917/(t + 232.75)$$

where P_v is the vapor pressure in mm Hg and t is the temperature in °C.

The vapor pressure of chlorine trifluoride between 192.7 and 284.6 K can be expressed by the following Antoine equation:

$$\log_{10} P_v = 4.31282 - [1182.409/(T - 10.335)]$$

where P_v is the vapor pressure in bar and T is the temperature in kelvin [40]. This equation predicts a normal boiling point of 285 K at sea level pressure. Data in Figure 6 were calculated using this equation.

Figure 6: Vapor pressure of chlorine trifluoride. (Graph created by Schmidt 2018, based on data from [40].)

The vapor pressure of ClF_3 in the temperature range from 299 to 422 K (26 to 149 °C), which extends into the critical range, can be expressed by [66]:

$$\log p = 4.8257 - 1363.1/T$$

where p is the vapor pressure in atm and K is the temperature in kelvin. The highest measured vapor pressure point was 3.838 MPa (556.7 psia) at 422 K (148.58 °C). The Trouton constant of ClF_3 is 20.8.

The vapor pressure of chlorine trifluoride was measured by a static-type apparatus over a fairly narrow temperature range at just above room temperature from 300 K to 317 K, with corresponding pressures from 0.1848 MPa to 0.3349 MPa [68]. The vapor pressure at 313.15 K was 0.2947 MPa. The experimental data were correlated in parallel

by both the Antoine and Frost–Kalkwarf equations:

$$\log_{10} P_v = a - b/(T + c) \quad \text{Antoine} \quad (1)$$

$$\ln p = a + b/T + c \ln T + d/T^2 \quad \text{Frost–Kalkwarf} \quad (2)$$

where p is the pressure in MPa and T is the temperature in kelvin. The deviations of both equations were less than $\pm 0.05\%$. For comparison and to make sure that the apparatus was working properly, vapor pressures of *n*-butane were measured in the same apparatus and agreed accurately with literature data. The coefficients for both equations are listed in Table 12.

Table 12: Parameters of vapor pressure equations for chlorine trifluoride in comparison with butane used for calibration of the apparatus.

Substance	Equation	a	b	c	d
<i>n</i> -Butane	1	3.07198	1004.78	−25.4810	
<i>n</i> -Butane	2	37.6216	−3990.58	−4.51131	20090.4
Chlorine trifluoride	1	3.38984	1048.94	−45.5987	
Chlorine trifluoride	2	61.4209	−5574.54	−7.81482	22625.9

Data source: [68]

Figure 7 shows a comparison of Sako’s data and the NIST vapor pressure data. Sako’s measurements showed a substantially lower vapor pressure than the NIST data.

Figure 7: Comparison of Sako’s [68] and NIST [40] vapor pressure data of chlorine trifluoride.

2.2.2.5 Viscosity of Chlorine Trifluoride

Data for the viscosity of liquid ClF₃ are summarized in Table 13.

Table 13: Dynamic viscosity of liquid ClF₃ (interpolated values).

Temperature		Dynamic viscosity η	
K	°C	mPa s	mPs
285	11.75	0.478	4.78
288	15	0.460	4.60
293	20	0.435	4.35
298	25	0.412	4.12
303	30	0.390	3.90
308	35	0.370	3.70
313	40	0.351	3.51
318	45	0.333	3.33
323	50	0.316	3.16

Data source: [69]

The following graph, Figure 8, was generated from these measured data. The data have been curve-fitted and can be expressed by the following equation:

$$\log \eta = -3.83031 + 430.517/T$$

where η is the dynamic viscosity in poise and T is the temperature in kelvin.

Figure 8: Dynamic viscosity of liquid chlorine trifluoride. (Graph created by Schmidt 2018, based on data from [69].)

Another very similar set of viscosity data for liquid ClF_3 was reported in [50], which seems to include the earlier data above (Table 14 and Figure 9).

Table 14: Viscosity of liquid chlorine trifluoride.

Temperature		Viscosity, η	
°C	K	mPa s	mPs
11.75	284.85	0.478	4.78
15	288.1	0.460	4.60
17.3	290.4	0.448	4.48
17.9	291	0.447	4.47
19.4	292.5	0.438	4.38
20	293.1	0.435	4.35
25	298.1	0.412	4.12
26	299.1	0.407	4.07
30	303.1	0.390	3.90
32.05	305.15	0.380	3.80
35	308.1	0.370	3.70
36.3	309.4	0.365	3.65
39.8	312.9	0.352	3.52
40	313.1	0.351	3.51
48	321.1	0.323	3.23
50	323.1	0.316	3.16

Data: [50]

Figure 9: Dynamic viscosity of liquid chlorine trifluoride. (Graph created by Schmidt 2018, based on data from [50].)

The viscosities of gaseous F_2 , ClO_3F , ClF , ClF_3 , ClF_5 , BrF_3 , and BrF_5 were measured over a temperature range from 323 to 423 K (50 to 150 °C) with a corrosion-resistant capillary viscometer [70]. From the experimental data obtained, the parameters σ , (ϵ/k) of the 6–12 Lennard-Jones potential (non-polar gases) and μ , σ , (ϵ/k) of the 3–6–12 Stockmayer potential (polar gases) could be calculated.

2.2.2.6 Surface Tension of Chlorine Trifluoride

The surface tension of ClF_3 between 273 and 323 K (0 and 50 °C) can be expressed by the following equation:

$$\sigma = 26.7 - 0.16t$$

where σ is the surface tension in dyn/cm accurate to within ± 0.2 dyn/cm and t is the temperature in °C. For conversion purposes, $1 \text{ dyn} = 10^{-5} \text{ N}$. From Banks' and Rudge's values (Loc. cit.) for the density of liquid chlorine trifluoride and values of the surface tension calculated from the above equation, the parachor for chlorine trifluoride has been calculated to be 111.5. Table 15 and Figure 10 compare measured and interpolated surface tension data:

Table 15: Comparison of measured and interpolated surface tension data of chlorine trifluoride

Temperature		Surface tension, dyn/cm	
K	°C	Observed	Calculated
273.2	0.0	26.6	26.7
275.7	2.5	26.3	26.3
277.2	4.0	26.0	26.1
282.1	8.9	25.35	25.3
282.2	9.0	25.15	25.3

315.2	42.0	20.0	20.0
320.2	47.0	19.1	19.2
323.1	49.9	18.7	18.7

Data source: [69]

Note: For conversion purposes, $1 \text{ dyn} = 10^{-5} \text{ N}$

Figure 10: Surface tension of chlorine trifluoride. (Graph created by Schmidt 2018, based on data from [69].)

2.2.2.7 Solubility and Miscibility of Chlorine Trifluoride

Liquid ClF_3 is completely miscible in a molar ratio of 1 : 1 with O_2F_2 at 180 K, with ClO_3F at 195 K or with H_2F_2 at 195 K, but forms two separate layers with NF_3 or OF_2 at 140 K, ClF at 174 K, F_2 at 185 K, or C_3F_8 at 235 K [41].

2.2.2.8 Thermal Conductivity of Liquid Chlorine Trifluoride

The thermal conductivity of chlorine trifluoride is difficult to measure because the surface of the instrument may become fluoridated while the measurement is in progress at higher temperatures. The thermal conductivity of saturated liquid chlorine trifluoride is illustrated in Figure 11. The thermal conductivity of liquid chlorine trifluoride can be calculated from the curve-fitted equation

$$\lambda = 4.74 \times 10^{-4} - 8.7 \times 10^{-7} t$$

where λ is the thermal conductivity in $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$ and t is the temperature in °C .

Figure 11: Thermal conductivity of liquid chlorine trifluoride. (Graph created by Schmidt 2018, based on data from [65].)

2.2.2.9 Heat Transfer Properties of Liquid Chlorine Trifluoride

The heat flux of liquid ClF_3 flowing through a tubing at a flow speed of 9.4 m/s (31 ft/s) as a function of the temperature differential is illustrated in Figure 12.

Figure 12: Limiting heat flux of liquid chlorine trifluoride. (Reproduced and modified from [65].)

The heat flux at the upper limit of nucleate boiling for chlorine trifluoride at three different flow velocities and four different bulk temperatures of 258, 308, 333, and 366 K (5, 95, 140, and 200 °F) is illustrated in Figure 13.

Figure 13: Heat flux of liquid chlorine trifluoride at the upper limit of nucleate boiling. (Reproduced and modified from [65].)

2.2.2.10 Thermodynamic Properties of Chlorine Trifluoride

Thermodynamic properties of chlorine trifluoride are required to calculate the theoretical rocket performance of propellant combinations with this oxidizer. Solid chlorine trifluoride undergoes an isothermal phase transition at 190.50 K that absorbs 1508 J/mol (360.5 cal/mol) [61, 71]. Thermodynamic properties of ClF_3 are summarized in Tables 16 and 17.

The molar heat capacities of liquid ClF_3 based on measurements by [61] are summarized in Table 18.

Table 16: Thermodynamic properties of chlorine trifluoride.

Property	SI Units	MKS Units	Source	Year	References

The heat capacity and the excess enthalpy of formation of gaseous chlorine trifluoride can be calculated from the following polynomial equations [40]:

$$C_p^\circ = A + B \times \tau + C \times \tau^2 + D \times \tau^3 + E/\tau^2;$$

$$H^\circ - H^\circ_{298.15} = A \times \tau + B \times \tau^2/2 + C \times \tau^3/3 + D \times \tau^4/4 - E/\tau + F - H$$

where the coefficients A through H are listed in Table 19 for two different temperature ranges, and where C_p is the heat capacity in J mol⁻¹ K⁻¹, H° is the standard enthalpy in kJ/mol, and τ is the temperature fraction in (K)/1000.

Table 19: Coefficients for heat capacity and enthalpy polynomial for gaseous chlorine trifluoride.

Temperature range, K	298–1100	1100–6000

Data source: [75]

In a critical review of the Scheer data, a correction was applied, which changed the entropy of the gas phase at 284.91 K to 66.64 $\text{cal mol}^{-1} \text{K}^{-1}$ [74].

The heat capacity of liquid ClF_3 was measured calorimetrically over a temperature range of 278.5 to 330.4 K (5.4 to 57.3°C) and can be expressed by the following polynomial equation [66]:

$$c_p = 0.4716 - 2.217 \times 10^{-3}T + 8.428 \times 10^{-6}T^2 - 9.453 \times 10^{-9}T^3$$

where c_p is the heat capacity in $\text{cal g}^{-1} \text{K}^{-1}$ and T is the temperature in kelvin. Figure 14 shows the same liquid heat capacity data as in Figure 15, but at a more detailed scale

Figure 14: Heat capacity of liquid chlorine trifluoride. (Based on data from [61] and [66].)

expansion and extending the earlier Grisard 1951 [61] measurements to higher temperatures. The solid line in Figure 14 is the result of least square curve fitting and the equation

$$c_p = 0.3025 + 2.43 \times 10^{-4}t + 7.5 \times 10^{-7}t^2$$

where c_p is the heat capacity in $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$ and t is the temperature in $^\circ\text{C}$. The triangles are the data from [61]. The circles are data obtained by Youel at Rocketdyne [66].

In the same 1967 report, and also shown in the 1969 publication, the heat capacity of solid ClF_3 was measured and curve fitted. The heat capacity of solid ClF_3 at temperatures in the range between 20 and 197 K (-253 and -76 $^\circ\text{C}$) can be expressed by the following equation:

$$c_p = -3.49 \times 10^{-2} + 3.53 \times 10^{-3}T - 3.07 \times 10^{-3}T^2 + 1.47 \times 10^{-7}T^3 - 2.57 \times 10^{-10}T^4$$

where c_p is the heat capacity in $\text{cal g}^{-1} \text{ K}^{-1}$ and T is the temperature in kelvin. The heat capacity of solid and liquid chlorine trifluoride as a function of temperature is illustrated in Figure 15.

Figure 15: Heat capacity of solid and liquid chlorine trifluoride. (Reproduced and modified from [66].)

Enthalpies of formation have been computed for ClF_n ($n=1-3$) using a density functional theory method [76]. The accuracy of the results was strongly dependent on the basis set quality and it was crucial to add at least one tight d function to the Cl atom. The atomization energies were corrected for scalar relativistic, core-valence, spin-orbit, thermal effects, and zero-point energy. The enthalpies of formation data calculated by this method shown in Table 21 were in very good agreement with experimental values, though suggesting that the Joint Army, Navy, Air Force (JANAF) values from [77] are slightly underestimated.

Table 21: Calculated enthalpies of formation of ideal gas ClF and ClF_3 .

Temperature, K	0	298.16			
Source	[76]	[76]	G2 DFT Method	[77]	[78]
Compound	Enthalpy of formation in kcal/mol				
ClF	-13.1	-13.1	-14.0	-12.0 ± 0.1	-13.3 ± 0.1
ClF_3	-38.2	-39.1	-38.4; -39.6	-38.0 ± 0.7	-39.3 ± 1.2
	Enthalpy of formation in kJ/mol				
ClF	-54.8	-54.9	-58.6	-50.2 ± 0.4	-55.6 ± 0.4
ClF_3	-159.8	-163.6	-160.7; -165.7	-159.0 ± 2.9	164.4 ± 5.0

The enthalpies of formation of ClF, ClF_3 , ClF_5 , ClFO, ClFO_2 , ClFO_3 , ClF_3O_2 , ClF_3O , and ClF_5O have been calculated with the help of atomization reaction, formation reaction, and modified formation reaction at the G3 and G3X levels [79]. The standard thermodynamic functions of the title compounds were evaluated and the results agreed well with the available experimental data. Results showed that ClF, ClF_3 , ClF_5 , and ClF_3O are stable at room temperature, but ClFO_2 , ClF_3O_2 , and ClF_5O may be stable only at a lower temperature. The original publication contained data in 100-K increments from 200 to 800 K, but for our summary we have extracted and are showing only the G3 data at 298 K for comparison in Table 22.

Experimental enthalpies of formation of three different chlorine fluorides measured by combustion reactions in two types of bomb calorimeters (high-frequency spark-ignited bomb and double compartment bomb) were ClF: $-58.1 \text{ kJ/mol} = -13.9 \text{ kcal/mol}$; ClF_3 : $-155.6 \text{ kJ/mol} = -37.2 \text{ kcal/mol}$; ClF_5 : $-239.3 \text{ kJ/mol} = -57.2 \text{ kcal/mol}$ [82].

Table 22: Calculated thermodynamic data of ideal gas chlorine fluorides and oxyfluorides in comparison with experimental data.

Compound	Enthalpy of formation, gas, kJ/mol			Heat capacity, J mol ⁻¹ K ⁻¹		Entropy, J mol ⁻¹ K ⁻¹	
	G3	Experimental	Source	G3	Experimental	G3	Experimental
ClF	-52.0	-56.0±0.4	[80]	31.3	32.1	217.1	217.9
ClF ₃	-149.9	-158.9±2.9	[77]	65.4	63.8	290.2	281.6

2.2.2.11 Optical Properties of Chlorine Trifluoride

Infrared Spectra of Chlorine Trifluoride

The IR spectrum of gaseous ClF₃ at five different sample cell pressures is shown in Figure 16.

The Raman and IR spectra of ClF₃ and BrF₃ gave strong support for a planar T-shaped molecule [84]. The fundamental vibrational frequencies of ClF₃ observed for the vapor were 326 (a₁), 364 (b₂), 434 (b₁), 528 (a₁), 703 (b₁), and 752 (a₁) cm⁻¹. The entropy S₀ for ClF₃, calculated statistically at the boiling point, 11.75 °C, was 66.60 cal mol⁻¹ deg⁻¹ compared with a value of 67.04 obtained from a revised calculation of this quantity from available thermal data. See also [85].

Infrared absorption bands observed for gaseous ClF₃ were characterized as follows (wave numbers in cm⁻¹) [86]: 518 s, 535 s, 694 vs, 703 vs, 713 vs, 741 s, 761 s, 957 m, 1022 m, 1223 s, 1273 w, 1451 s, 1466 s, 1488 s, 1505 s. Measurements for solid ClF₃ showed only absorption bands at 499 m, 508 m, 604 vs, 630 vs, 765 m, 770 w.

The IR and Raman spectra of ClF₃ have been studied in the vapor phase and frequencies for the six fundamental vibrations of each molecule have been assigned based on a C_{2v} symmetry [83]. For ClF₃ the frequencies were 752.1, 529.3, and 328 (a₁), 702 and 442 (b₁) and 328 (b₂) cm⁻¹.

The IR spectra of matrix-isolated ClF₃ have been investigated in the region from 800 to 33 cm⁻¹ [87]. All six fundamentals have been observed in Ar and N₂ matrices for ClF₃ and BrF₃, which are planar T-shaped molecules. Both molecules showed only small gas-matrix frequency shifts, and multiplet structure for both molecules suspended in Ar matrices may be understood in terms of isotope and matrix site effects. Several absorption bands found at low matrix-isolation ratios were attributed to dimers and a tentative partial vibrational assignment was presented.

Legend: A: Baseline, B: 2 mm Hg, C: 10 mm Hg, D: 17 mm Hg, E: 145 mm Hg, F: 450 mm Hg, G: Detail of 700 cm^{-1} peak at 2 mm Hg pressure at higher resolution

Raman laser spectra of ClF_3 have been investigated between 13 and 293 K and IR spectra were recorded and analyzed at liquid nitrogen temperature [88]. The vibrational study of ClF_3 showed an associated state in the liquid and a solid-solid transition at 192.6 K with an intermediate phase covering 5 K. A dynamical model for association was set up to explain both nuclear magnetic resonance (NMR) and Raman spectra. The associated species in the liquid were assumed to be intimately connected with the structure of the intermediate phase; moreover, the splitting of transitions into doublets allowed one to expect molecular interactions. See also [89].

Ultraviolet Spectra of Chlorine Trifluoride

Chlorine trifluoride photolyzes easily with even mild UV irradiation. As a result of this photolysis, one will thus always contain spectra that contain both ClF_3 and the $\bullet\text{ClF}_2$ free radical. UV excitation of ClF_3 in mixture with difluorine and/or other fluorides is a method for the synthesis of other fluorine compounds that are (were) of interest as rocket propellant oxidizers. The UV absorption spectra of these compounds must be known to select the optimal wavelength of the UV source used for the photosynthesis.

Microwave Spectra of Chlorine Trifluoride

A microwave spectrometer designed for the study of the microwave spectra of corrosive fluorine compounds has been used to observe and measure a portion of the microwave spectrum of chlorine trifluoride [90]. A number of transitions were identified, and from these the moments of inertia and quadrupole coupling coefficients of both $^{35}\text{ClF}_3$ and $^{37}\text{ClF}_3$ could be obtained. An intensity alternation was observed showing that the ClF_3 molecule has a C_{2v} axis and is planar. The moments of inertia confirm this and further showed that ClF_3 has a distorted "T" structure with one short (1.598 Å) and two long (1.698 Å) Cl—F bonds. The angle between the two different kinds of Cl—F bonds is $87^\circ 29'$.

The rotational spectrum of the T-shaped ClF_3 molecule was recorded for both ^{35}Cl and ^{37}Cl isotopomers in selected regions between 66 and 581 GHz [91]. The observation of transitions involving J and K_a quantum numbers of up to 82 and 27 respectively permitted the first centrifugal distortion analysis for this molecule. Most of the rotational transitions showed resolved hyperfine splitting due to the ^{35}Cl or ^{37}Cl nucleus yielding, under consideration of previous data, accurate quadrupole coupling constants and, for the first time, nuclear spin-rotation coupling constants. Although the former have been interpreted in terms of ionic bonding of the two different ClF bonds comparable with that in the ClF molecule, the latter were used to calculate nuclear magnetic shielding tensors.

NMR Spectra of Chlorine Trifluoride

Indirect spin-spin coupling tensors, J , are of importance in interpreting NMR spectra. For example, a great deal of experimental and theoretical work has focused on the characterization of J couplings observed across hydrogen bonds. Similar couplings may occur between fluorine bonds and contribute to the association of molecules and the low vapor pressure of ClF_3 and other fluorides. Symmetry properties of indirect nuclear spin-spin coupling tensors can be calculated by a first principles method and results for ClF_3 and OF_2 were shown in Bryce and Wasylishen [92]. Measured J_{iso} (^{35}Cl , ^{19}F) in ClF_3 is ± 260 Hz and J_{iso} ($^{19}\text{F}_{\text{eq}}$, $^{19}\text{F}_{\text{ax}}$) in ClF_3 is ± 403 Hz and the calculated numbers were very close. See Muetterties and Phillips [93, 94].

Gas-phase ^{19}F NMR spectra of ClF_3 at 56.4 MHz over a range of partial pressures (300–1300 mm Hg) were measured, extending to sufficiently low pressures that the shielding and spin-spin coupling constants $(\sigma_A - \sigma_B)/(1 - \sigma_B) = 125.88 \times 10^{-6}$, $|J| = 441 \pm 8$ cps could be regarded as true molecular quantities [95]. Small systematic relaxation effects in the multiplet splitting were identified and eliminated by graphical procedures. NMR data were also given for ClF_3 as a liquid and as a solute in CCl_4 and CCl_3F . Although these spectra were similar enough to that of the gas to indicate that the T-structure persisted in all these phases, there were clear trends in σ_B and J for the sequence: gas, liquid solutions, pure liquid. These trends may result from the existence in the condensed phases of local structure similar to that found in the crystal.

2.2.2.12 Electrical Properties of Chlorine Trifluoride

Electrical Conductivity of Chlorine Trifluoride

Pure ClF_3 at $273\text{ K} = 0^\circ\text{C}$ has a very low specific conductance of $3 \times 10^{-9}\ \Omega^{-1}\text{ cm}^{-1}$, much lower than that of BrF_3 . The electric conductivity of liquid ClF_3 was measured in the temperature range from 261.8 to 143 K (-11.3 to -130°C ; well below freezing point), also in comparison with BrF_3 [96, 97]. The data are illustrated in Figure 17. The two curves shown are from the same sample, one before (Δ) and one after ($\circ$) what was an intended purification cycle, but owing to the longer dwell time in glassware, more contaminants had been leached from the glass walls, allowing the conductivity to go up

Figure 17: Electrical conductivity of liquid and solid chlorine trifluoride. (Reprinted and adapted from [97], with permission from © 1966 American Chemical Society.)

instead of down as expected. The electrical conductivity underwent steep changes in the area where the sample froze or supercooled. The electrical conductivity of frozen ClF_3 has a negative temperature coefficient.

Dielectric Constant of Chlorine Trifluoride

The dielectric constant of ClF_3 was determined at 9400 MHz by measuring the change in the resonant frequency of a cavity when it is filled with the vapor [98]. Corrections were made for the amount of dimer formed. The monomer molar polarization was best represented by $P = 15,944 + 1882.0/T$, where T is the temperature in K and P is the molar polarization in cm^3 . The dipole moment was 0.554 Debye unit. The average dimer molar polarization was found to be 49.8 cm^3 , assuming no dipole moment.

The dielectric constant of liquid ClF_3 has been measured in the range 273 to 315 K (0 to 42°C) at several frequencies and may be expressed by the equation [99, 100]:

$$\varepsilon = 4.754 - 0.018t$$

for ClF_3 , where ε is the dielectric constant (dimensionless) and t is the temperature in °C. The results indicated that these substances are associated in the liquid state.

The dielectric constants of gaseous ClF_3 (Table 23), BrF_3 , and IF_5 were measured in the vapor phase using a refractivity method [101]. Dielectric constants were measured using the heterodyne beat method. The fixed oscillator was crystal-controlled at 500 kHz. Introduction of the gas into the measuring cell increased the capacitance in the tank circuit of the variable frequency oscillator: the precision capacitor was then adjusted to restore the original beat frequency. The atomic polarizations of ClF_3 and BrF_3 were estimated from the observed molar refractions (10.34 and $15.48 \text{ cm}^3/\text{mol}$) and distortion polarizations (15.94 and $18.98 \text{ cm}^3/\text{mol}$). The atomic polarizations of BrF_3 and IF_5 were assumed to be the same as those of ClF_3 (5.5) and BrF_5 (3.5) respectively.

Table 23: Dielectric constant and molar polarization of gaseous chlorine trifluoride.

Temperature K	Dielectric constant ($1 - \varepsilon$) $\times 10^6$	Molar polarization P_M cm^3/mol
319.3	2825	24.2
351.8	2490	23.6
375.8	2293	23.3
413.3	1929	21.7

Data source: [101]

Dipole Moment of Chlorine Trifluoride

The dipole moment of ClF_3 was calculated from the dielectric constant. The molar refractions, atomic polarizations and average dipole moments (from molar polarizations at three or four temperatures) are shown in Table 24. The dipole moments listed have a probable error of about ± 0.12 D. The average dipole moment of ClF_3 is shown in Table 24 in comparison with dipole moments of BrF_3 and IF_5 .

Table 24: Molar refractions, atomic polarizations, and dipole moments of halogen fluorides.

Compound	Molar refraction M_{RD} , cm^3/mol	Atomic polarization	Dipole moment, D
Chlorine trifluoride	10.34	5.5	0.65
Bromine trifluoride	32.92	5.5	1.19
Iodine pentafluoride	19.17	3.5	2.18

Data source: [101]

Chlorine trifluoride is known to have a planar T-configuration with the central Cl—F bond shorter than the other two by $0.1 \text{ \AA}$ and angles F—Cl—F of about 87° and the small dipole moment agrees with that structure.

2.2.2.13 Magnetic Properties of Chlorine Trifluoride

Chlorine trifluoride and several of the other halogen fluorides examined were all diamagnetic. The specific magnetic susceptibility of chlorine trifluoride was -0.287×10^{-6} c.g.s. units and the molar susceptibility was -26.5×10^{-6} c.g.s. units [102].

2.2.2.14 Molecular Structure of Chlorine Trifluoride

The molecular structure of ClF_3 is planar, in which the three fluorine atoms are grouped asymmetrically around the central atom (Figure 18). It is a curious fact that the dipole moment of 0.554 D found for chlorine trifluoride is less than the moment of 0.881 D found for chlorine monofluoride. It is not clear whether this can be attributed to a fluorine to chlorine electron transfer or if it should be interpreted as a cancellation of the Cl—F₁ moment by chlorine lone electron pair hybrids.

Figure 18: Molecular structure of chlorine trifluoride

The chlorine trifluoride molecule is planar with the point group symmetry mm . The crystal structure of frozen ClF_3 is orthorhombic with the following cell constants: $a = 8.826 \pm 0.01 \text{ \AA}$, $b = 6.09 \pm 0.01 \text{ \AA}$, $c = 4.52 \pm 0.01 \text{ \AA}$. X-ray diffraction (XRD) of frozen ClF_3 at 153 K (-120°C) showed that there is one short Cl—F bond ($1.621 \text{ \AA}$) and two long Cl—F bonds ($1.716 \text{ \AA}$), and the F—Cl—F angle was $86^\circ 59'$ [103]. Similar results were obtained by microwave measurements: the one short Cl—F bond was $1.598 \text{ \AA}$, the two long Cl—F bonds were $1.698 \text{ \AA}$, and the $\angle\text{FCIF}$ angle was $87^\circ 29'$, [90]. A number of transitions have been identified, and from these the moments of inertia and quadrupole coupling coefficients of both $^{35}\text{ClF}_3$ and $^{37}\text{ClF}_3$ were obtained.

Molecular orbital (MO)-Linear Combination of Atomic Orbitals (LCAO)-self-consistent field (SCF) calculations of ClF_3 showed that the T-shaped nuclear configuration can be satisfactorily explained without the use of chlorine 3d orbitals. The calculated charge distribution was found to be similar to that postulated by the Gillespie and Nyholm model but with excess electronic charge on the fluorine atoms [104, 105].

Extended basis set calculations using the CPF method for ClF and ClF_3 were done to clarify discrepancies between experiment and previous computations [106]. Good agreement was found for ClF, but agreement was slightly poorer for ClF_3 , as only the 2dlf basis could be used: $r_{\text{eq}} = 160.7 \text{ pm}$, $r_{\text{ax}} = 171 \text{ pm}$, $\angle\text{FCIF} = 87.1^\circ$. The computation of $\Delta E(\text{ClF}_3 \rightleftharpoons \text{ClF} + \text{F}_2)$ turned out to be difficult: $\Delta E = 59.3 \text{ kJ/mol}$ on the 2dlf level. Various extensions of the basis set led to improvements of a few kJ/mol; the estimate for the 3d2flg basis became $\Delta E \approx 80 \text{ kJ/mol}$. The remaining discrepancy between theory and experiment is attributed to incomplete error cancellation within CPF arising from the very different binding in ClF_3 (three-center-four-electron bonding) compared with ClF and F_2 .

Chlorine trifluoride has a tendency to form dimers. It is believed that the dimer is produced by the formation of bridges from the fluorine atoms between two molecules, the electron pairs from the fluorine atoms occupying 3d orbitals of the chlorine atoms. This configuration can be considered to be derived from the octahedral system, with two electron pairs occupying two axial positions; the dimer therefore has a planar structure. Because of the increased stability of such a configuration, ClF_3 tends to form dimers.

Molecular dynamics computational simulations of liquid ClF_3 at three average temperatures, 217, 260, and 287 K, were conducted in order to explain the temperature variations of its properties in the liquid state [107]. Gas-phase microwave and solid-state XRD studies had already shown that the ClF_3 molecule has a planar distorted “T” structure of C_{2v} symmetry, with the bond lengths and angles $r_{24} = r_{34} = 1.698 \text{ \AA}$, $r_{14} = 1.598 \text{ \AA}$, $r_{45} = 0.36 \text{ \AA}$, and $\angle 142 = \angle 143 = 87^\circ 28'$. On the basis of the results from laser Raman spectroscopic study of ClF_3 , Drifford et al. suggested the presence of dimers in the liquid state. Evidence for dimers existing in the liquid state has also come from the IR spectra of ClF_3 in an argon matrix ([87]). The dimer geometric configuration drawn based on the calculated contact distances was found to be in good agreement

with the results of matrix isolation IR and laser Raman spectroscopic studies. See also [108–110]. The main reason for studying the molecular structure of ClF_3 is to understand the electronic nature of Cl–F bonds and to plan for the synthesis of more highly fluorinated chlorine fluorides such as ClF_5 or ClF_7 .

2.2.3 Chemical Properties of Chlorine Trifluoride

2.2.3.1 Purity Requirements for Chlorine Trifluoride

Chlorine trifluoride that was procured by the US Government for nuclear fuel processing or as a rocket propellant had to meet the purity requirements of MIL-P-81399 – Propellant, Chlorine Trifluoride, which required a ClF_3 assay of 99 mass-% minimum, a maximum HF content of <0.4 mass-%, a maximum limit of the sum of $(\text{ClO}_2\text{F} + \text{ClO}_2) < 0.2\%$, and a maximum limit of the sum of $(\text{ClF} + \text{Cl}_2 + \text{F}_2) < 0.4\%$. This specification is no longer maintained.

2.2.3.2 Decomposition of Chlorine Trifluoride

When discussing the decomposition of ClF_3 , one must keep in mind that under certain conditions ClF_3 is associated with a dimer. The dimer would have to dissociate before the monomer starts decomposing. The reversal of the formation kinetics is dependent on the decomposition kinetics of ClF_3 and ClF_5 [38]. The thermal dissociation of ClF_3 behind incident shock waves has been studied in the temperature range 800–1300 K [111]. The course of the dissociation was followed by means of UV absorption spectroscopy centered at 2200 Å. Initial slope measurements gave a value of

$$k_1 = 10^{13.5 \pm 0.4} \exp(28200 \pm 1700)/RT \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

for the rate constant of the reaction

where M is a third body or the wall. The collision efficiency of ClF relative to argon was found to be 35 ± 5 to 1. Evidence was presented that favors a heat of formation for ClF_2 of $-19 \pm 2 \text{ kcal/mol}$ at 0 K.

2.2.3.3 Photolysis of Chlorine Trifluoride

Photolysis of chlorine trifluoride, in particular in the presence of excess fluorine, would be a promising first step in the synthesis of higher fluorides such as ClF_5 and ClF_7 .

The dynamics of the 248-nm excimer-laser-induced photodissociation of ClF_3 have been investigated by observation of the Cl atoms by time-resolved laser magnetic resonance [112]. In the presence of Cl_2 , photolytically produced F atoms interacted with Cl_2 to produce Cl atoms. The quantum yields for F and Cl atom formation were 1.85 ± 0.25 and < 0.02 respectively. By examination of the electronic configuration of

the excited state of ClF_3 , the primary photodissociation products are predicted to be $\cdot\text{ClF}_2$ and $\cdot\text{F}$.

The chemical kinetics of the UV photochemical formation and destruction of ClF_3 were investigated experimentally to obtain information relating to optimal conditions for the formation of ClF_3 and the reaction mechanisms involved [58, 59]. The photolysis of ClF_3 was also investigated because it limits the yield of ClF_3 and ClF_5 production by photochemical methods.

2.2.3.4 Radiolysis of Chlorine Trifluoride

Chlorine trifluoride used to reprocess nuclear reactor fuel rods that are still highly radioactive is potentially subjected to radiolysis by the nuclear radiation. It was explained that thermal decomposition of ClF_3 under the conditions of fuel rod reprocessing would be dominant over radiolytic decomposition [113].

2.2.3.5 Reactions of Chlorine Trifluoride with Inorganic Compounds

The most probable inorganic compound for chlorine trifluoride to react with is moisture from atmospheric air or water squirted by a HazMat response team on a chlorine trifluoride leak. The reaction of ClF_3 or ClF with H_2O is highly exothermic and can lead to ignition of flammable materials in the vicinity of where the reaction takes place [114–117]. The overall reaction can be expressed by

The partial hydrolysis of chlorine trifluoride most likely take place via intermediate formation of chlorosyl fluoride, ClOF [118]. Another of the intermediate reaction products was perchloryl fluoride ClO_2F , which subsequently also hydrolyzed with additional water. Other reaction steps leading to intermediate products are:

Adding these reactions together yields the overall reaction under conditions of excess ClF_3 :

The heat of reaction was calculated to be 243.2 kJ/mol. Under conditions of excess water, the reaction would be

and the heat of reaction for excess H_2O would be 228.0 kJ/mol.

Although some metals such as magnesium, aluminum, and copper form a protective fluoride film that can halt further action, at elevated temperatures these metals combine explosively with chlorine trifluoride.

An investigation of the kinetic rates of four gas-phase reactions involving chlorine monofluoride and chlorine trifluoride showed that radioactive chlorine does not exchange at a measurable rate between Cl_2 and ClF_3 in the liquid phase at 193 K (-80°C) or in the gas phase up to 438 K (165°C) [119]. The reaction of Cl_2 with ClF_3 to form ClF appeared to be essentially homogeneous in the gas phase and proceeded at a conveniently measurable rate in the temperature range 453–523 K (180 – 250°C). It followed a second-order rate expression within experimental error with activation energy of 84.4 kJ/mol (20.18 kcal/mol) and activation entropy of 12.3 e.u. The exchange of radioactive chlorine between ClF_3 and tagged ClF has been followed in the temperature range 476–518 K (203 – 245°C). The exchange appeared to be homogeneous with a rate proportional to the product of the square roots of the reactant concentrations and an activation energy of 66.5 ± 4 kJ/mol (15.9 ± 1.0 kcal/mol).

The reaction of excess ClF_3 with HONO_2 is different from what one might expect. FCIO_2 and ClF were the observed products and not ClFO (which is unstable):

The reactions of ClF , ClF_3 , ClF_5 , and ClO_2F with a monofunctional hydroxyl compound ($\text{HO}-\text{NO}_2$) and a bifunctional hydroxyl compound ($\text{H}-\text{O}-\text{H}$) were studied in systematic series of experiments in an effort to find commonalties and differences between the various reactant pairs [120]. The first step of reactions of chlorine fluorides with a hydroxyl compound is usually the abstraction of HF :

The nature of reaction products depended on which reactant was used in excess. The reactions of chlorine fluorides with HNO_3 are of interest because they might form new solid oxidizers. The reactions with water inevitably occur with atmospheric moisture or they are evaluated as a method for disposal of excess halogen fluorides or as scrubber fluids when venting pressurant gas from pressurized tanks after a test. The reaction products are listed in Table 25. All reactions were very violent and sometimes had to be chilled by dipping the reaction vessel (a U-tube cold trap) into a bath of liquid nitrogen. The partial hydrolysis of chlorine fluorides does not offer a synthetic route toward chlorine oxyfluorides, except for ClO_2F .

Table 25: Reactions of chlorine fluorides with hydroxyl compounds.

Halide	Hydroxyl compound	
	Nitric acid	Water
ClF	With an excess of ClF, reaction products were ClONO ₂ and HF	With excess water, products were Cl ₂ :ClO ₂ :O ₂ in a mol ratio 2:1:0.25, HF, and some Cl ₂ O
ClF ₃	With an excess of ClF ₃ , reaction products were NO ₂ F, ClO ₂ F, ClF, and HF. With an excess of HNO ₃ , products were ClO ₂ (1.7 mmol), ClONO ₂ (1.7 mmol), HF, N ₂ O ₅ , and O ₂	
ClF ₅	Excess ClF ₅ with HONO ₂ : two layers formed. Products were ClO ₂ F (1.66 mmol), unreacted ClF ₅ (2.4 mmol), NO ₂ F (3.3 mmol), and HF. ClF ₅ with excess HONO ₂ : The reaction products consisted of O ₂ (0.42 mmol), ClO ₂ F (0.55 mmol), ClONO ₂ (0.29 mmol), ClO ₂ (0.36 mmol), N ₂ O ₅ , and HF	Reaction of ClF ₅ with excess HOH: The products consisted of ClO ₂ (1.35 mmol), ClO ₂ F (0.35 mmol), ClO ₃ F (0.18 mmol), O ₂ (<0.5 mmol), and HF
ClO ₂ F	Reaction of ClO ₂ F with excess HONO ₂ : The reaction products were O ₂ (0.25 mmol), ClO ₂ (0.48 mmol), unreacted ClO ₂ F (1.86 mmol), N ₂ O ₅ , unreacted HONO ₂ , and HF

Tetrafluorochloronium(III) and Difluorochlorate(III) Complexes from Reactions of Chlorine(III) Trifluoride with Inorganic Compounds

In parallel with efforts to develop ClF₃ and ClF₅ as oxidizers in liquid rocket propellant combinations, a significant effort has been made to synthesize solid compounds derived from ClF₃ or ClF₅ that could potentially be used as oxidizers in solid rocket propellants or as solid sources of gaseous fluorine in a gas generator formulation. Starting with the known observation that ClF₃ undergoes homolysis (similar to bromine trifluoride)

and knowing that it is an electrolyte [121], it has been observed that electrical conductivity increases substantially when adding Lewis acids such as BF₃, AsF₃, or SbF₅. There is a long series of reports describing the progress in this pioneering work on halogen fluoride chemistry, also including nitrosonium and nitronium salts and salts of the new tetrafluoroammonium cation [NF₄]⁺. The driving force behind this effort spanning more than three decades was the desire to develop a high-energy replacement for ammonium perchlorate as an oxidizer in solid propellants. Some of this series of investigations started at Stauffer Chemical in Richland, CA, and was later continued at Rocketdyne in Canoga Park, CA. The following references give a summary of reports on this effort, but not all this wealth of fluorine chemistry material could be absorbed

into this book [86, 122–155]. It would require a book of its own to extract from these reports the many different synthetic methods used and the properties of the many new compounds synthesized. Whatever was reported in quarterly progress reports sometimes was superseded in final reports. Quarterly reports contain only preliminary information that may later be superseded and updated in subsequent quarterly or final reports. Sometimes, the Defense Technical Information Center (DTIC) website had only the quarterly reports listed and the bibliographic information on the associated final report could not be found. In those cases we have included quarterly and interim reports in our summary bibliography. In many cases an abstract was not available so one can only guess that the work was on high-energy oxidizers derived from ClF_3 , ClF_5 , and other fluorine compounds, including noble gas fluorides and noble gas oxyfluorides and dioxygenyl salts. Each of these reports deals with at least ten different topics and it would be difficult to separate them and discuss each topic in detail. In some cases the author was not listed and the table shows the author only as “Anonymous.” The list of references above may serve as a starting point for those who intend to follow up on this development of high-energy oxidizers. The continued effort at Rocketdyne in Canoga Park, CA, resulted in the synthesis of many new additional fluoronium and fluorometallate complex salts as candidates for high-energy solid propellant oxidizers. The results were reported both as contractor reports to the sponsoring agency and some of the work was also published in the open periodical literature. In those cases, preprints of the publications were attached as appendices to the annual reports. It would fill an entire book if we tried to summarize all the work that was done on complex fluoride salts. One of the reactions of K_2MnF_6 with SbF_5 led to the first chemical (not electrochemical) synthesis of elementary fluorine, a remarkable discovery that coincided with the centennial of the first discovery of difluorine by Moissan in 1886 [156].

The chemistry of ionic fluoro complexes with chlorine, nitrogen, or oxygen as the central atom of one ion and boron, aluminum, phosphorus, arsenic, or antimony in the other ion is (literally) very complex, and it would be very difficult to give a complete overview here about which salts were synthesized, what their properties are and if they can be used as rocket propellants. We leave this task to other, more qualified chemists. What is needed for an investigator starting to work in this area is a comprehensive survey of the thermal stability of these sometimes very labile salts. Some salts were only stable at low temperatures and only just long enough to have their IR and XRD spectra taken.

Difluorochlorinium Salts

Pure ClF_3 at $273\text{ K} = 0^\circ\text{C}$ has a very low specific conductance of $3 \times 10^{-9}\ \Omega^{-1}\text{ cm}^{-1}$, much lower than that of BrF_3 . If one adds SbF_5 to ClF_3 , making a 0.564-molar solution of $[\text{ClF}_2^+][\text{SbF}_6^-]$, the specific conductance increases to $6.65 \times 10^{-3}\ \Omega^{-1}\text{ cm}^{-1}$. Vapor pressure measurements also indicate compound formation of the type $[\text{ClF}_2^+][\text{AsF}_6^-]$ and

$[\text{ClF}_2^+][\text{BF}_4^-]$. One can even perform “neutralization” reactions with cationic and anionic ClF_3 salts in ClF_3 as the solvent:

If one measures electrical conductivity as a function of reagent addition, the stoichiometric ratio coincides with a sharp minimum of electrical conductivity [157, 158]. Other fluoronium compounds synthesized are $[\text{ClF}_2]_2[\text{SnF}_6]$ and $[\text{ClF}_2]_2[\text{TiF}_6]$. The following fluoronium salts $[\text{ClF}_2][\text{SbF}_6]$, $[\text{ClF}_2][\text{AsF}_6]$, KIF_6 , SbBrF_8 , and AsBrF_8 were patented as oxidizers for rocket propellants [159], but it may be difficult to find a binder that does not prematurely react with these compounds.

^{19}F NMR spectra were measured for HF solutions of ClF_6^+ , ClF_4^+ , ClF_2^+ , ClO_2F_2^+ , and ClF_2O^+ and for NF_2O^+ salts in comparison to chemical shifts for ClF and ClF_3 in order to compare the structures of these cations [160]. Several exchange processes between the cations and anions and the solvent were observed, depending on the temperature and the acidity of the solvent. The acidity of the HF solvent was varied by the addition of AsF_5 . It was shown that ClF_6^+ is octahedral and splitting owing to both $^{35}\text{Cl}-\text{F}$ and $^{37}\text{Cl}-\text{F}$ spin-spin coupling has been observed for the first time.

Solid AsF_5 complexes with various chlorine fluorides were the suspect contaminants that deposited and clogged pipes in a UF_6 isotope separation plant [161]. Their dissociation pressures were measured and methods for removal were tested. See also [162–167].

Tetrafluorochlorate(III) Salts

Tetrafluorochlorate(III) anions form stable salts with Lewis bases [168–170]. See also [171].

A tetramethylammonium salt of the tetrafluorochlorate(III) anion was prepared by metathetical reaction of $[\text{N}(\text{CH}_3)_4]\text{F}$ with CsClF_4 in acetonitrile as the solvent [172]. This salt is thermally stable up to 373 K and, most surprisingly, is not shock sensitive.

Another potential oxidizer is nitrosonium tetrafluorochlorate $\text{NO}^+ \text{ClF}_4^-$ [173]. It can be prepared by reaction of nitrosyl fluoride and chlorine trifluoride at temperatures below 273 K. The compound is a white, crystalline solid and a powerful oxidizer. It ignites hypergolically with many organic fuels. The enthalpy of formation was estimated as $\Delta H_f^{298} = -287 \text{ kJ/mol}$ (-68.6 kcal/mol). Attempts to prepare nitronium tetrafluorochlorate were unsuccessful.

Hexafluorochlorate(V) Salts

Although hexafluorochlorate(V) salts initially could not be obtained in bulk, Raman spectra and ^{18}F isotope exchanges supported the existence of the hexafluorochlorate(V) anion ClF_6^- [174].

The increasing order of oxidizing power from anion to neutral molecule to cation can be used for the synthesis of superoxidizers. This approach is based on the prepa-

ration of high oxidation state transition metal fluoride anions by high-pressure/high-temperature fluorination reactions with elemental fluorine and their conversion into superoxidizing cations by adding strong Lewis acids in anhydrous HF solution, for example, the synthesis of ClF_6^+ and BrF_6^+ from NiF_3^+ [175].

Reactions of Chlorine Trifluoride with Organic Compounds

Chlorine trifluoride is a very strong oxidizer. Organic compounds, even graphite and wood charcoal, react vigorously with chlorine trifluoride and burst into flames. Some of these reactions approach explosive violence. Most organic hydrogen-containing compounds, predominantly all hydrocarbons, will ignite spontaneously with ClF_3 , as will all the hydronitrogens such as ammonia or hydrazine. That makes it of interest as a hypergolic start fluid for bipropellant rocket engines and solid propellant motors. The combustion reactions of chlorine trifluoride with hydrocarbons and other rocket fuels will be discussed in the future *Encyclopedia of Hypergolic Bipropellant Combinations*.

Chlorine trifluoride is thermally stable at room temperature and does not decompose during storage. The main long-term storage problem is contamination by metal fluorides leached from the container walls. Only above 573 K (300 °C) will ClF_3 begin to decompose into chlorine monofluoride and fluorine; above 873 K (600 °C) the decomposition is nearly complete.

2.2.3.6 Analysis of Chlorine Trifluoride

Formerly, when wet chemistry dominated the quality control laboratory, the assay of gaseous ClF_3 was analyzed by reacting a nitrogen-diluted gas sample with potassium iodide solution and titrating the liberated iodine with sodium thiosulfate. However, free chlorine or fluorine present as contaminants in ClF_3 would cause an erroneously high ClF_3 assay. The chlorine interference can be avoided by first reacting the gas with an excess of dry, pulverized sodium chloride, pumping off the residual gas, and then titrating an aliquot of a solution of the salt [176]. In this method, ClF_3 vapor is passed through a known weight of dry sodium chloride, contained in a copper tube. Sodium fluoride is produced and the free chlorine that is liberated is absorbed in sodium hydroxide solution. After decomposition of the sample, chlorine and fluorine are determined in the sodium chloride/fluoride mixture and in the sodium hydroxide solution. From the known weight of sodium chloride used, the chloride contributed by the sample can be calculated. The chloride can be determined by Mohr's volumetric titration method and the fluoride can be titrated with thorium nitrate using alizarin red as indicator.

To avoid wet chemical methods, the analyst will prefer a quick gas chromatographic analysis of chlorine fluorides that can be readily separated from another and from accompanying contaminants, even in the presence of strongly corrosive agents such as HF [177–181]. The methods discussed here for ClF_3 can be equally as well used

for other volatile fluorides, such as ClF_5 , OF_2 , NF_3 , N_2F_4 , and ClO_3F . The column packing used for the gas chromatography (GC) analysis of non-metallic fluorides was Kel-F[®]-oil on Kel-F[®] powder. The GC columns, fittings, and detectors were made mostly of nickel and nickel alloys. Flame ionization detectors are not as suitable for fluorine compounds as they are for chlorine compounds (insecticides), such that thermal conductivity detectors or gas density balances are preferred for this type of work, although the hot filaments may not last very long when exposed to the corrosive gases [182–188]. Gas density bridges are suitable for the analysis of corrosive gases by GC because the hot filament does not come in contact with the sample gas.

The GC determination of trace gaseous impurities in highly reactive fluorine compounds such as ClF_3 presents unique requirements for both equipment and techniques. Analyzing trace gases at the low ppm level requires special equipment such as a custom-designed system with backflush column-switching techniques to protect the columns and detectors. A thermal conductivity detector with nickel filaments was used to determine ppm levels of impurities in ClF_3 [189].

Nuclear magnetic resonance (NMR) is useful for identifying the structures of halogen fluorides, analysis of the mixture ratios in binary mixtures of fluorides, and determination of unwanted impurities (see Furnish [190], Muettterties and Phillips [94], and Williams [191]).

The now obsolete Military Specification MIL-P-81399A recommended a near-IR spectrophotometric method for analysis of HF in ClF_3 . Other volatile contaminants (ClO_2F , ClO_2 , ClF , Cl_2 , F_2) can be determined by gas chromatography.

When attempting to analyze ClF_3 by mass spectrometry, reactive species often react prematurely in the inlet to a mass spectrometer before a clean mass spectrum can be obtained. Cooling the mass spectrometer inlet will allow the sample to enter the ionization chamber unadulterated. Mass spectra of ClF_3 and several other reactive fluorides were obtained using this method [45]. Operating at low temperatures will also allow one to examine the sample for dimer association in the vapor phase.

The ionization of ClF_3 under electron impact leads to the formation of the following ions, at the indicated appearance potentials (eV): ClF_3^+ : 13.0 ± 0.2 ; ClF_2^+ : 12.8 ± 0.3 ; ClF^+ : 12.7 ± 0.3 eV [192]. The ionization potential of ClF_3 , obtained in earlier work, 13.0 ± 0.2 eV, was close to the value of the vertical ionization potential, 12.88 ± 0.01 eV, obtained from photoelectron spectroscopic studies.

Detection of Chlorine Trifluoride in the Air

Chlorine trifluoride and other non-metal fluorides under evaluation as rocket or chemical laser propellants can be detected in trace amounts in the air of working areas to assure the safety of the working personnel and provide warning in case of a leak.

Dosimeter badges and portable detection devices capable of measuring ppm levels of ClF_3 , ClF_5 , NF_3 , N_2F_4 , or OF_2 are needed in work areas where these gases are used. Despite the great energy of reaction released when these compounds act as oxi-

dizers in rocket engines, they are kinetically somewhat inert at room temperature ppm dilutions. Most of the fluoride oxidizers react with Br^- or I^- salts yielding F^- , which can be detected with fluoride-specific reactions. A dosimeter could be constructed by using either the lanthanum-alizarin fluorine blue color reaction or a F^- ion-specific electrode. More expensive techniques for developing a portable detector would be an electron-capture gas chromatograph or a pulsed-leak quadrupole mass spectrometer [193].

Sub-ppm concentrations of ClF_3 in a 1-mL air sample introduced directly into a gas chromatograph without requiring time-consuming concentration procedures could be detected rapidly with an electron capture detector [194]. A linear response was obtained in the range of 0.05 to 1.0 ppm by volume and detectability of less than 0.01 ppm was indicated. A 10-ft $\times$ 1/4-in stainless steel column filled with 5% DC-200 on 60/80 Chromosorb G mesh was used at room temperature. The carrier gas was 95% argon/5% methane at a flow rate of 200 mL/min. An electron capture detector was operated at 50 V RF without purge gas.

2.2.4 Handling of Chlorine Trifluoride

Liquid ClF_3 is considered more reactive than vapor-phase F_2 in all kinds of chemical reactions, as more mols of fluorinating agent are present per unit area of reactant surfaces if liquid ClF_3 is spilled on it. Also, liquid ClF_3 may demonstrate even higher reactivity in certain circumstances than liquid fluorine, as the F_2 liquid temperature is cryogenic, thus reducing its activity potential. See also [195–197].

2.2.4.1 Materials of Construction for Chlorine Trifluoride

Metals. Although chlorine trifluoride is very reactive, many metals with a smooth surface will form a protective fluoride film and become passivated against further attack by dry ClF_3 . Metal powders or samples with a large surface area can autoignite spontaneously in ClF_3 . Similar to the passivation in elemental fluorine, metals such as copper, nickel, bronze, Monel, or stainless steel form a passivating layer of metal fluorides. If the metal parts are subjected to bending or vibration, and the passivation layer flakes off, the same precautions as already discussed with elemental fluorine apply here when in contact with chlorine trifluoride (gaseous or liquid).

In most cases, Monel[®] and nickel would be the preferred materials of construction. Aluminum, copper, magnesium, titanium, niobium (=columbium), and molybdenum and their alloys and several stainless steels have been investigated with regard to their resistance against chlorine trifluoride and perchloryl fluoride [198]. A few aluminum, copper, magnesium alloys, and stainless steel with low carbon content were found to be suitable for ClF_3 service, but only for temperatures up to 303 K (30 °C). In all cases, freshly machined metal surfaces have to be slowly passivated with gaseous ClF_3 before they are placed into service at full pressure. Typical alloys of Al, Cu, Mg,

Ni, low-carbon steel, and stainless steel were resistant to ClF_3 or ClO_3F and their mixtures at 303 K, and even under severe mechanical shock [199]. The metals must be clean and dry, but no special passivation was required. An HNO_3/HF pickling acid cleaning step was recommended for stainless steels and high-Ni alloys. Ti, Nb, Mo, and graphite were rapidly attacked by ClF_3 . Measurements of compatibility and corrosion rates of nine welded alloys of aluminum, nickel, and stainless steel, stressed and unstressed, in ClF_3 , ClO_3F , and 25% $\text{ClO}_3\text{F}/75\% \text{ClF}_3$ at 303 and 339 K (30 and 66 °C) were investigated and showed that corrosion rates at 303 K (30 °C) were all less than 0.1 mil/year (1 mil = 1/1000 in); [200]. At 339 K (66 °C), corrosion in ClF_3 and ClO_3F was less than 0.1 mil/year except for CRES-410 where it was 1–2.2 mil/year. In ClO_3F at 339 K (66 °C) corrosion was normally below 0.5 mil/year, but with moisture present, rates up to 8.3 mil/year were observed. A Teflon orifice in a flow test fixture was attacked by ClF_3 . Liquid impingement jets of ClF_3 and ClO_3F at 30 m/s (100 ft/s) had no effect on these metals, except for a slight pit in aluminum 2014-T6 with ClF_3 . Liquid cavitation of ClF_3 and ClO_3F in an aluminum tube caused no metal change.

The kinetic rates for reaction of ClF_3 with copper were of the same order of magnitude as those observed with elemental fluorine [201]. At atmospheric pressure the coating consisted of copper(II) fluoride and copper(I) chloride.

Chlorine trifluoride by itself or ClF_3/F_2 mixtures can be used for passivating metal surfaces prior to use with either fluorine or chlorine trifluoride, but contamination by organics must be avoided [202, 203].

Titanium, niobium (=columbium), molybdenum, or graphite were strongly attacked by ClF_3 . For the evaluation of candidate materials of construction it is essential to test the compatibility, not only with stagnant but also with flowing ClF_3 . At Reaction Motors, several different metals were tested for ClF_3 resistance in a closed loop with recirculating liquid ClF_3 for later use in tanks for storable missile propellants [204]. Monel, nickel, 300-series stainless steel, brass, and copper were suitable materials of construction even under these operating conditions. Aerosols of suspended particles of boron, boron carbide, and most metal powders suspended and fluidized in a stream of nitrogen, that were candidates for an air/metal or Mars atmosphere (CO_2)/metal ramjet, ignited and burned in chlorine trifluoride [205, 206]. The only exception that failed to ignite was a 200-mesh nickel powder.

For additional information on materials compatibility with chlorine trifluoride, consult [207, 208].

Failures in the weld areas of nickel-plated steel pipe carrying chlorine trifluoride prompted an investigation to determine the effect of weld composition on corrosion by ClF_3 [209]. Monel/steel and nickel/steel alloys of composition to simulate weld overlays were tested to determine their corrosion rates in ClF_3 at 200 °F and 300 °F. For both nickel/steel and Monel/steel, the corrosion rate was higher at the higher temperature. For nickel/steel alloys at compositions up to 50% Fe, which would cover a range considered normal for welding, the corrosion rate would be within acceptable limits.

For Monel/steel alloys, compositions up to 35% Fe had an acceptable corrosion rate. Above this, the corrosion would be greater than a tolerable amount.

A survey of pre-treatment methods for metal surfaces that are to come into contact with ClF_3 and other storable propellants suggested that for most other oxidizers special pre-treatments are not necessary as long as the surfaces are free of contaminants, but in the case of ClF_3 , OF_2 , and FLOX it may be advantageous to practice gradual exposure of metal surfaces to the fluorine compound to ensure deactivation of contaminants that may have resisted the cleaning process [210]. A general procedure for metal systems to be used with ClF_3 , OF_2 , or FLOX proceeds with the following steps: descale, degrease, dry, and control gradual fluorination. The thickness and adherence of fluoride films determines corrosion rates during storage.

Non-metals. Chlorine trifluoride is so reactive that even quartz wool or glass wool can burn in it with a bright flame. Perfluorinated polymers such as polytetrafluoroethylene (PTFE) or poly chlorotrifluoroethylene are compatible with stagnant gaseous or liquid ClF_3 at room temperature, but some precautions against their use in flowing ClF_3 are appropriate. Once ignited, even perfluorinated polymers can burn in ClF_3 with a vigorous flame reaction. Gaskets on flanges or valves can be made from soft copper, aluminum 2S, lead, or PTFE with calcium fluoride as the filler material. Metal-coated polymers, including Teflon[®] and Viton[®], were tested as materials for O-rings and propellant expulsion bladders in propellant tanks in pressure-fed systems [211, 212]. Same as with fluorine systems, it is difficult to find lubricants that are truly compatible with ClF_3 . One of the lubricants tested was Permatex[®] No.2. As a precaution, the first two turns on the inside of a threaded connection should not be lubricated at all.

Of all the perfluorinated greases that were tested for their suitability for use with ClF_3 , only very few were found to be resistant and some ignited.

Poly(tetrafluoroethylene) and poly(chlorotrifluoroethylene) can be used with ClF_3 or ClO_3F and their mixtures at up to 303 K but mechanical shock must be avoided [199]. Both plastics absorb moderate amounts of the oxidizers and can undergo structural changes and embrittlement. These plastics are best used only in the vapor phase with these gases. They should never be used with these oxidizers under heat, shock, or fast flow conditions.

O-ring seals of selected elastomeric and compliant materials were evaluated for resistance to ClF_3 in a simulated end-use test at 296 K (73 °F) [213]. The candidate elastomers were placed under compression in closed cells and exposed to the liquid and vapor of liquid ClF_3 for extended periods of time. Rate of propellant loss through the seal and the change in physical properties of the seal materials were determined.

2.2.4.2 Components for Chlorine Trifluoride Systems

Quick disconnect couplings were developed for use with fluorine and fluorine-containing oxidizers for a typical upper stage (e.g., NOMAD) oxidizer fill-and-drain application [214, 215].

2.2.5 Handling of Chlorine Trifluoride

When preparing a listing of the relative hazards of rocket propellants, ClF_3 was ranked as the most dangerous storable rocket propellant oxidizer [216, 217].

Recommendations for the safe handling of chlorine trifluoride are given in [218–221]. There are several books that summarize recommendations for the safe storage and handling of reactive materials and some include chapters on ClF_3 , for instance, [222].

One of the very best presentations on the hazards of handling ClF_3 was made by representatives of Air Products at the CCPS 2003 Symposium [62]. It is richly illustrated with dramatic images showing the effect of gaseous or liquid ClF_3 on various materials of construction, protective clothing, and flesh (using a dead chicken as a surrogate for human flesh).

It is especially important that all components that come into contact with ClF_3 are thoroughly cleaned prior to use in order to remove grease, dust, stains, oil, or other dirt. Even the smallest contamination can trigger a reaction with ClF_3 that then makes a rapid transition to the bordering metals. New components, such as valves or rotameters, may have to be disassembled before use so that all nooks and crannies can be thoroughly cleaned and degreased. After the system is fully assembled and leak-checked, the slow and controlled passivation can proceed similar to the stepwise method already described in *Encyclopedia of Oxidizers* in the chapter “Fluorine.” The system is first filled with dry nitrogen, and the nitrogen is gradually replaced with chlorine trifluoride, with 1-h hold periods allowed between each successive increase in ClF_3 concentration. Once the desired concentration and full operating pressure is achieved, the system should be left idle under this condition for an hour and after that time the gas can be vented to a scrubber.

If liquid ClF_3 has to be transferred from one tank to another, dry nitrogen gas can be used as the pressurant gas. Storage areas for large ClF_3 tanks must meet certain setback requirements from populated and inhabited areas. When selecting the location for ClF_3 tank farms, the prevailing wind direction needs to be taken into consideration. Storage buildings must be constructed from non-combustible materials and wood, tar paper, and combustible plastics must be avoided.

Potential by-products of hydrolysis of ClF_3 include chlorine oxyfluorides and explosive chlorine oxides [223]. Traces of these contaminants can be found in ClF_3 that was not kept in carefully dried containers and came into contact with atmospheric moisture.

It is very difficult to neutralize a pool of spilled ClF_3 because it reacts with most chemicals that it comes into contact with. If the incorrect neutralization agent is used, instead of neutralizing the spill, it may burst in flames, which aggravates the situation. Damage control procedures for spills of chlorine trifluoride for shipboard firefighting equipment and protective clothing were evaluated, and methods and materials for neutralizing spilled propellants were proposed [224]. Powdered inorganic fluorides may be used as absorbents to prevent spreading of pools of liquid chlorine trifluoride and to facilitate removal of the chlorine trifluoride for disposal. None of the fluorides tested showed any tendency to form compounds with chlorine trifluoride and thus lower its vapor pressure in a closed container. Water spray, as well as finer sprays, is effective in dissipating chlorine trifluoride by controlled chemical reaction. Sodium- and potassium bicarbonate-based dry chemical powder fire extinguishants produced enough heat of reaction that their principal effect was to cause rapid vaporization of pools of chlorine trifluoride.

2.2.5.1 Gelled Chlorine Trifluoride

In an effort to reduce the leakage hazard and rate of evaporation of liquid chlorine trifluoride, a variety of gelling agents have been tested with ClF_3 . Other gelling agents proposed for non-metallic fluoride liquid oxidizers were barium hexafluoroantimonate and barium hexafluorobismuthate [225].

2.2.5.2 Personnel Protection Gear for the Handling of Chlorine Trifluoride

During the transfer of ClF_3 , the personnel in the tank farm or test site must wear protective clothing consisting of fire-proof and acid-proof garments [219, 220]. The recommended protective ensemble consists of a tightly sealed one-piece suit, a gas mask, and neoprene gloves. An oxygen respirator should be kept at the ready on stand-by.

Neoprene and Armalon (woven polytetrafluoroethylene laminated with a continuous sheet of polytetrafluoroethylenepropylene) showed promise as materials for the construction of protective coveralls for ClF_3 handling [226]. It was emphasized that these materials must be kept free of local contamination with substances easily ignited by chlorine trifluoride, such as oil and grease, since, once ignited, the uncontaminated portion may continue to burn, even in dilute chlorine trifluoride vapor. Armalon showed greater resistance to chlorine trifluoride over a wider range of concentrations than neoprene. Butyl rubber-coated cloth and vinyl-coated glass cloth were readily ignited by dilute chlorine trifluoride vapor, and they are unsuitable for protective clothing.

A rocket propellant handlers' suit for protection from chlorine trifluoride and elemental fluorine was developed and operationally tested by the US Air Force (USAF) [227]. The exposed components of this garment were made of perfluoropolymers and stainless steel. The complete suit and sample components were exposed to both

gaseous fluorine and liquid chlorine trifluoride. The suit reacted with liquid chlorine trifluoride and therefore failed to pass the operational test.

Various types of personnel protective gear, including polycarbonate face shields, latex, nitrile rubber, and leather gloves, neoprene, Tyvek[®], and Nomex[®] clean room suits, lab equipment plastics, and building materials were tested for impingement of liquid and (in a separate test) gaseous ClF_3 [62, 228]. Most of the materials ignited instantly as shown by a number of photographs in the presentation. The worst reaction was between a Tyvek polyethylene clean room suit material, that was first wetted with ClF_3 and then had contact with water. The explosive reaction of ClF_3 combined with H_2O tore the suit to pieces.

For protective clothing for the handling of chlorine trifluoride, see also Pharo [229], and Pharo and Nenno [230].

2.2.5.3 Spill Neutralization of Chlorine Trifluoride

Similar to recommended precautions in the handling of elemental fluorine, small leaks of ClF_3 can be neutralized with sodium carbonate powder from a dry powder fire extinguisher. Water helps only if it is applied in great excess. If the rate of water application is insufficient, the exothermic hydrolysis of ClF_3 can aggravate instead of remediate the severity of the situation. Water is so reactive with ClF_3 that it actually worsens the problem situation in the event of a ClF_3 leak. One example of the unique design thinking for ClF_3 equipment is that ClF_3 manufacturers did not recommend installing a water sprinkler inside test facilities for fire mitigation. Chlorine trifluoride is so water reactive that alternative means are necessary for the prevention and mitigation of fires, both internal and external to areas where ClF_3 is used. This position was supported in 1997 by a major industrial insurance company's specific recommendation to prohibit sprinklers in ClF_3 gas cabinets used for the semiconductor industry.

Chlorine oxides are also potential by-products of the hot reaction of ClF_3 with sodium bicarbonate or sodium carbonate, such as that applied with dry chemical fire extinguishers. Besides sodium bicarbonate and sodium carbonate, a large number of other chemicals were tested for neutralization of ClF_3 spills [231].

Instrumented spill tests were conducted using 60 to 800 kg of rocket propellants and the effects on test stand structures, protective clothing, and caged test animals at different distances from the event were studied.

Disposal of Surplus Chlorine Trifluoride

Chlorine trifluoride vapors that are vented from a pressurized tank can be passed through soda lime traps or caustic scrubbers or (in remote areas) flared off in a propane flare stack.

2.2.6 Toxicity of Chlorine Trifluoride

Chlorine trifluoride has been described as the most aggressive, toxic, and dangerous halogen fluoride. It is by one order of magnitude more toxic than HF.

2.2.6.1 Maximum Allowed Exposure Levels of Chlorine Trifluoride

The recommended threshold level (TLV) time-weighted average (TWA) for an 8-h work day is 0.1 ppm with a ceiling notation. In converting ClF_3 concentrations from ppm to mg/m^3 , 1 ppm (vol) is equal to $3.78 \text{ mg}/\text{m}^3$.

The Immediately Dangerous to Life and Health (IDLH) concentration for chlorine trifluoride is 20 ppm, even lower than that of fluorine, which is 25 ppm [232–235].

The 1-h LC₅₀ of chlorine trifluoride is 178 ppm in mice and 230 ppm in monkeys. If a concentration of 50 ppm ClF_3 in air is exceeded for more than 30 to 120 min, the exposure may be immediately fatal. In animal tests the toxic action is obvious after only 3 min at 100 ppm, and immediate at 500 ppm. The symptoms are suffocation, coughing, swelling of the mucous membranes in the eyes and nostrils, and permanent opacity of the cornea.

2.2.6.2 Animal Exposure Tests with Chlorine Trifluoride

Chronic exposure of different groups of test animals to 1.17 ppm, 6 h/days, 5 days/week, resulted in the first fatalities in a group of dogs after 115 days. Under the same conditions, starting with a group of 20 rats, 6 out of 20 rats passed away during a 6-month exposure test [236–239]. The toxicity of ClF_3 is caused primarily by its corrosive effects on surfaces of contact, on the skin, in the eyes, in the nasal passages, and in the lung. The damage caused by ClF_3 is in part a function of its diverse hydrolysis products, which may form in varying proportions in the atmosphere, in pulmonary gases or during decontamination procedures. In the vapor phase, ClF_3 may decompose to ClF , Cl_2 , ClOF , ClO_2F , ClO_3F , ClO_2 , and HF, depending on the availability of water. Of these, Cl_2 , HF, and ClO_2 are probably of greatest significance. Inhalation exposure of rats to 800 ppm ClF_3 for 15 min was always lethal and 13 min of contact was usually survived [240, 241]. Four-hundred ppm was usually lethal after 35 min of exposure. ClF_3 exposures resulted in severe mucosal inflammation and burning of the skin, followed by corneal ulceration. Pulmonary release of $^{14}\text{CO}_2$ from injected [^{14}C]bicarbonate was decreased after ClF_3 inhalation, as was blood pH, indicating pulmonary impairment. Of the principal hydrolysis products considered, ClO_2F decomposes too rapidly in the presence of water vapor for study. In separate tests, ClO_3F was always lethal at exposures of 5000 ppm $\times$ 15 min and 2000 ppm $\times$ 40 min with extensive methemoglobin formation, and essentially non-lethal at 2000 ppm $\times$ 25 min and 1000 ppm $\times$ 60 min. ClO_2 lethality is comparable with that of ClF_3 on a chlorine equivalent basis. ClF_3 lethality is comparable with that of HF, on a fluorine equivalent basis. See also [242].

2.2.6.3 Olfactory Threshold Chlorine Trifluoride

In real life working areas are evacuated as soon as some of the very sensitive instrumented monitors trigger an alarm or as soon as the odor of chlorine trifluoride is detected. The olfactory threshold has not been accurately pinpointed, but it is substantially below the 1 h of exposure to a hazardous concentration.

2.2.6.4 Dermal Effects of Chlorine Trifluoride

Even if working personnel wear full respiratory and eye protection, ClF_3 vapors can cause serious chemical burns on exposed, unprotected skin. The burns are similar to those caused by HF and heal only very slowly. The same first aid measures as outlined in the chapter “Fluorine” should also be taken in case of exposure to ClF_3 . The physician-in-charge of the test area must read up beforehand on the most recent recommended techniques for the treatment of HF burns.

An accident involving chlorine trifluoride occurred on 28 July 2006 in a semiconductor factory in Hsinchu (Taiwan), resulting in a large release of the highly reactive material and causing chemical burn injuries to several workers [243]. ClF_3 is used primarily as an *in situ* cleaning gas in the manufacture of semiconductor silicon-wafer devices. The health hazards of probable decomposition/hydrolysis products from ClF_3 were evaluated based on their basic physicochemical properties and occupational exposure limits. The occupational exposure assessment was further discussed to understand secondary hazards caused by HF and fluorides from the decomposition/hydrolysis products of ClF_3 .

In order to simulate the impingement of a spill of chlorine trifluoride on human skin, a piece of dead chicken (feathers removed, ready for cooking) was used as a surrogate human skin for an impingement test [62, 228]. The spilled liquid ClF_3 ignited instantly as soon as it contacted the skin of the dead chicken (Figure 19).

Figure 19: Impingement of liquid chlorine trifluoride on a chicken carcass (reproduced from [228] with permission from ASTM International).

2.2.7 Environmental Effects of Chlorine Trifluoride

If accidentally released into the atmosphere, chlorine trifluoride is not going to persist very long. Gradual hydrolysis will convert it to hydrogen chloride and HF, which are of course also very unpleasant environmental pollutants.

Several volatile inorganic fluorides were reviewed for their chemical, physical, and toxicological properties [244, 245]. The compounds were nitrogen trifluoride; tetrafluorohydrazine; chlorine trifluoride; bromine pentafluoride; oxygen difluoride; HF, and fluorine. Seeds and seedlings of bean, corn, pea, squash, and Sudan grass were exposed to air or water mixture of these compounds. Exposure of dry seeds to less than 500 ppm of either BrF_5 or ClF_3 in air drastically reduced their subsequent germination even when the exposure time was for less than 1 h. Exposures of plant seedlings to gaseous ClF_3 in air at 500 and 2000 ppm for 5 min resulted in extensive destruction of the plants. Plant injury was caused by irrigation of plant seedlings with solutions formed by the reaction of ClF_3 or BrF_5 with water. The exposed seeds and seedlings were analyzed for fluoride content.

Chlorine trifluoride was used in the gaseous diffusion process to fluorinate uranium yellow cake (U_3O_8) on its way to enrich ^{235}U at two plants in the US, one in Portsmouth, OH, and the other in Paducah, KY. ClF_3 was shipped to the two gaseous diffusion plants as compressed liquid in cylinders. These cylinders were stored on-site until they were emptied into large storage tanks that hold about 57 m^3 of ClF_3 liquid under its own vapor pressure. An accidental breach of a ClF_3 storage cylinder or tank would result in a release of ClF_3 vapor to the atmosphere, which is a concern for plant managers and safety engineers because of its extreme toxicity. An atmospheric dispersion model including ClF_3 chemical reactions with water vapor and thermodynamic processes in the atmosphere after an accidental release has been developed [246]. Initial model runs simulated the rapid formation of HF and ClO_2 after an atmospheric release of ClF_3 . At distances beyond the first several meters from the release point, HF and ClO_2 concentrations pose a greater threat to human health than do ClF_3 concentrations. For most of the simulations, ClF_3 concentrations rapidly fell below the IDLH requirement. For releases occurring in ambient conditions with low relative humidity and/or ambient temperature, ClF_3 concentrations exceeded the IDLH requirement by up to almost 500 m.

2.2.8 Accident History of Chlorine Trifluoride

One major incident involving ClF_3 that occurred during the liquid rocket propellant era is relatively famous (infamous) in the industry [62, 228]. In the 1960s, a US chemical company was a major supplier of ClF_3 for US governmental applications. They had an incident at one of their chemical facilities when personnel for the first time loaded a 1-ton steel container with liquid ClF_3 for bulk shipment. The container had been cooled with dry ice to perform the liquid transfer and help to make the product safer to handle, as the ClF_3 vapor pressure would be only about 0.7 kPa (0.1 psia) in the

sub-cooled state. However, the dry ice bath embrittled the steel container wall and, while maneuvering the full container onto a dolly, it split open and instantaneously released 907 kg (2000 lb) of cold ClF_3 liquid onto the building floor. The material “consumed through” (i.e., reacted with) the 30-cm (12-in) thick concrete floor and through about another 90 cm (36 in) of gravel underneath the spill. The fumes that were generated (chlorine trifluoride, HF, chlorine, hydrogen chloride, silicon tetrafluoride, etc.) severely corroded everything that was exposed. One eyewitness described the incident by stating “*The concrete was on fire!*”.

An accident involving chlorine trifluoride occurred on 28 July 2006 at a Hsinchu (Taiwan) semiconductor factory, resulting in a large release of the highly reactive material and causing chemical burns injuries to several workers [243].

2.2.9 Other (Non-rocket) Applications of Chlorine Trifluoride

The first large-scale application of ClF_3 was for military purposes. The Germans produced ClF_3 in tonnage quantities for military use during WW-II to use in flame-throwers based on the liquid’s extreme hypergolic ignition with fuels and as a general incendiary material.

Halogen fluorides have been evaluated as selective fluorinating agents for the synthesis of organic mono- and poly-fluoro-compounds [31].

Chlorine trifluoride instead of elemental fluorine can be used in the processing of uranium oxide (yellow cake) or the reprocessing of spent nuclear reactor fuel elements. The phase diagrams of ClF_3/UF_6 mixtures were therefore determined in order to be able to separate the reactants and reaction products [50, 60].

Chlorine trifluoride can be added to military shaped charges to increase the penetration power of shaped metal jets through steel plates in heavily armored tanks.

In a similar metal-cutting application, jets of hot liquid ClF_3 released at the bottom of oil wells would cut the steel casing tubing wall and/or a jammed drill rod where an extremely rapid and vigorous reaction can cleanly cut the metal in less than 1 s. The tubing or rod could then be withdrawn from the well and recovered.

Chlorine trifluoride is widely used as a non-plasma etching or cleaning gas, especially in semiconductor and microelectromechanical manufacture. Chemical vapor deposition processes require periodic cleaning of the chamber to remove the material that deposits on the walls [247]. *In situ* cleaning of the tool is desirable because the solid residues on the chamber interior are removed from the walls without dismantling the tool or risking personnel exposure to the hazardous residues or cleaning agents. *In situ* cleaning also yields quicker turn-around time for the tool to resume wafer processing. Fluorine atoms readily react with these solid residues to form volatile reaction products that can be purged and evacuated from the system. The primary advantage ClF_3 has over other gaseous fluorine cleaning sources (such as NF_3 , C_2F_6 , or CF_4) is that the high reactivity of ClF_3 allows the operation to be accomplished at relatively low temperatures, without requiring plasma or high temperature heating to disassoci-

ate it for use during the cleaning process. The use of vapor-phase ClF_3 for CVD chamber cleaning has demonstrated the ability to prolong chamber component life through the lack of high temperature or plasma use, and tool dismantling requirements. To minimize the damage to the vapor deposition equipment, the cleaning reagent must be able to react without the need for ion bombardment to create F atoms. Chlorine trifluoride is now widely used to clean semiconductor process tools *in situ*. At least chlorine trifluoride is not an ozone layer-destroying chemical like NF_3 . It would hydrolyze and be rained out before it has a chance to reach the upper atmosphere. Chlorine trifluoride that was used as an etchant and cleaning agent in the semiconductor industry has occasionally caused accidents [243].

2.3 Chlorine Pentafluoride

Chlorine pentafluoride, also known as ClF_5 , CPF, “Compound A”, “Fluoridyne,” CAS RN [13637-63-3] or [53120-06-2] is definitely the chlorine fluoride that would make the best rocket propellant oxidizer. Unfortunately, it is not as readily available as chlorine trifluoride and is more difficult to produce. At one time, it was predicted that for large-scale production, the price of ClF_5 would be not much different from that of ClF_3 or F_2 . When a German book on rocket propellants was written in 1967, chlorine pentafluoride had been discovered only a few years earlier and was still quite sensational. Very little was known about chlorine pentafluoride back in 1967. The code name for chlorine pentafluoride in those days was “Compound A.” It was sometimes only referred to under its confidential code name, Compound A, and the identity of Compound A was not revealed until many years later. Now, this section of properties is 40 pages long and there will be additional sections in future volumes of this book on rocket propellant combinations with ClF_5 as the oxidizer, which would add to this page count. There was a lot of interest in the potential use of ClF_5 as a rocket propellant and some of the early work in the US remained classified confidential for a long time. Only several decades later has some of the information become available to the general public.

There exist several good summary reports on chlorine pentafluoride that are recommended as a starting point for further in-depth study and that have served as a source for the current book [248–252].

2.3.1 Preparation of Chlorine Pentafluoride

Chlorine pentafluoride can be prepared from fluorine and chlorine trifluoride with thermal [253, 254], ultraviolet at 101 kPa with a 2:1 excess of fluorine [255], or electrical glow discharge activation [256, 257], or by the reaction of platinum hexafluoride with chlorine trifluoride [258]:

or by fluorination of alkali metal tetrafluorochlorate salts [257]

In one experiment, 76 g (0.5 mol) of dry CsF was reacted with 50 g (0.55 mol) of ClF_3 in an autoclave at 353 K (80 °C) for 4 h. After cooling, 15 L (0.67 mol) of fluorine gas was condensed into the autoclave and heated to 423 K (150 °C) for 22 h. After removal of the excess fluorine, 26 g (0.2 mol) of pure ClF_5 could be distilled out of the reactor into a cold trap. The yield was 40% of theory. With KF instead of CsF, the yield was only between 10 and 25%. The thermal, high-pressure process developed by Rocketdyne was scaled up to a pilot-plant scale and Rocketdyne was the main supplier of ClF_5 in the US while the evaluation as a rocket propellant was in full swing in the 1970s and 1980s. Rocketdyne built a pilot plant that was able to produce 12 lb/day in a continuous-flow process. There is a long series of reports covering this work [142, 259–263]. Several of these reports also include work on other oxidizers. From the titles alone, it was not clear if the work was on ClF_5 or ClO_3F , or both. There may be some overlap with information that should have been referenced in the perchloryl fluoride section but the reports were already summarized here.

Chlorine pentafluoride was synthesized by electrolysis from the $\text{HF}/\text{NaF}/\text{Cl}_2$ system [264]. Syntheses were conducted both with and without a gas electrode under various experimental conditions.

The kinetics of photochemical ClF_5 formation from ClF_3 and F_2 were examined at temperatures between 289 and 343 K (16 and 70 °C) using light with a wavelength of 365 μm [265]. The quantum yield of the reaction was always below 1. At 303 K the optimal value was 0.5 molecules of $\text{ClF}_5/h\nu$. ClF_5 formation was not by a chain reaction. Oxygen exerted a strongly inhibiting effect on this reaction.

It had been known for several decades that the reaction of fluorine with alkali metal chlorides would produce alkali metal tetrafluorochlorates, but the remaining gas phase had not been analyzed until it was found that it contained chlorine pentafluoride according to the reactions [266, 267]:

The reaction was conducted with an $\text{F}_2:\text{KCl}$ molar ratio of 5:1 at 473 K (200 °C) for 8 h and gave a yield of 65%. Molar ratios in the range from 12:1 to 3:1, temperatures in the range from 373 to 573 (100 to 300 °C), and reaction durations from 4 to 112 h were investigated but did not improve the yield. The particle size of KCl (75 or 350 μm) had no apparent effect on the yield. If one starts with KBr instead of KCl, similar reactions lead to the formation of bromine pentafluoride. More specifically, potassium chloride (0.25 mol) was placed in a 1-L stainless steel cylinder, 1.25 mol of fluorine was con-

densed at 77 K (−196 °C). When the mixture was allowed to warm to room temperature, a sudden exotherm occurred near room temperature. Then the reactor was heated to 473 K (200 °C) for 8 h. After cooling to an ambient temperature, the cylinder was attached to a vacuum line and cooled to 139 K (−134 °C). The excess fluorine was slowly bled and pumped off through a 139 K (−134 °C) trap into a 77 K (−196 °C) trap. The 139 K (−134 °C) trap and the reaction cylinder were warmed to ambient temperature and their volatile contents were transferred to a stainless steel storage cylinder. The product was identified as chlorine pentafluoride by its infrared bands at 732 and 786 cm^{-1} . No chlorine trifluoride was noted in the infrared spectrum of the majority of the samples. Molecular weight determinations by the vapor density method gave a value of 126 ± 2.5 , which was close to the calculated value, 130.45. The high-resolution ^{18}F NMR spectrum identified the substance as ClF_5 .

Chlorine pentafluoride can also be prepared by an electrolytic process from chlorine or chlorine trifluoride and HF [268, 269]. Electrofluorination of ClF_3 in anhydrous HF as an electrolyte and nickel electrodes resulted in the formation of ClF_5 in a divided or an undivided electrolytic cell. The yields of ClF_5 , based on coulombs in the electrical current, were of the order of 25 and 50% respectively in the undivided and the divided cell. Fluorine, nickel fluoride, and small quantities of chlorine–oxygen–fluorine compounds were also formed at the anode. At the cathode, hydrogen, hydrogen chloride, and chlorine were formed depending on the degree of mixing of anolyte and catholyte. The rate of ClF_5 formation was found to be a function of the concentration of ClF_3 in the electrolyte. From an analysis of polarization data, it was concluded that the mechanism involved the anodic oxidation of fluoride ion to some form of active fluorine, followed by its reaction with ClF_3 to form ClF_5 .

In the thermal autoclave reaction of the elements, the main disadvantage of all these methods is a relatively low space–time yield (quantity of ClF_3 converted into ClF_5 per unit volume in unit time), due to either a relatively low yield of chlorine pentafluoride or to a long reaction time. At higher temperatures, ClF_5 decomposes just as fast as it forms [270]. The space–time yield can be improved by nickel difluoride, which is a very effective catalyst [271]. The highest space–time yield ($143 \text{ g L}^{-1} \text{ h}^{-1}$) was observed at 523 K (250 °C) with a mol ratio $\text{ClF}_3 : \text{F}_2 = 1 : 5$ and an initial pressure of 10.3 MPa (102 atm, measured at 295 K = 22 °C). However, in this case only about 70% of ClF_3 was converted into ClF_5 . Despite the lower space–time yield, for the laboratory scale preparation synthesis at 473 K (200 °C) and a mol ratio 1 : 10 or 1 : 5 seems to be more suitable, because under these conditions the conversion of ClF_3 into ClF_5 is practically complete.

Separation of unreacted chlorine trifluoride from the chlorine pentafluoride product can be achieved by fractionated condensation [272, 273]. According to Smith [253], chlorine pentafluoride was discovered when fluorine and chlorine trifluoride in a molar ratio of 14 : 1 were heated for 1 h to 623 K (350 °C) at 25.2 MPa (250 atm = 3670 psia). Based on mass spectrometric analysis of the reaction product, the product that was separated by fractionated condensation consisted essentially of ClF_5 with small amounts of unreacted ClF_3 . A sample that had undergone additional

purification and contained only very little ClF_3 was a white solid at 77 K (-196°C) and melted to form a colorless to pale yellow liquid at 173 K (-100°C). The vapor pressure of the ClF_5 liquid was 5 to 6 times higher than that of ClF_3 .

Chlorine pentafluoride can be prepared in high purity and good yield by the fluorination of ClF_3 at 195 K (-78°C) with dioxygen difluoride O_2F_2 [274]. The yield of ClF_5 by this method is quantitative. The procedure illustrates the general utility of O_2F_2 in high-valency fluoride synthesis.

A process for the continuous production of ClF_5 on an industrial scale can be carried out by continuously passing fluorine as one reactant and chlorine, chlorine monofluoride, or chlorine trifluoride as the other reactant into a reaction chamber adjacent to the lower end of the chamber, maintaining the temperature and pressure in the reaction chamber sufficiently high to effect a reaction between the reactants to form gaseous chlorine pentafluoride in a mixture with gaseous fluorine ($373\text{--}553\text{ K} = 100\text{--}280^\circ\text{C}$ and $2.27\text{ MPa} = 330\text{ psi}$) [275, 276]. Products are withdrawn from the upper end of the chamber and fed into a collecting chamber near the upper end of the condensing chamber. The temperature in the condensing chamber is kept sufficiently low to achieve condensation of chlorine pentafluoride from the reaction mixture. The condensed chlorine pentafluoride is withdrawn from the condensing chamber as a liquid, and the uncondensed gas is continuously recirculated to the reaction chamber. The yield of ClF_5 can be increased by using excess fluorine, e.g., twice the stoichiometric amount of F_2 .

2.3.2 Physical Properties of Chlorine Pentafluoride

The molecular mass of ClF_5 is 130.44 g/mol. It contains 27.179% Cl and 72.821% F. The discovery of ClF_5 was the most fascinating news for rocket propellant chemists in the 1960s. More detailed summaries of the physical properties of chlorine pentafluoride have been published in the interim. The physical properties of chlorine pentafluoride (Table 26) are no longer shrouded in secrecy and are now widely available.

As of 1968, at the time of the first edition of a German book on rocket propellants, the only detailed publication on properties of chlorine pentafluoride was the paper by Pilipovich et al. [257], but more physical properties were determined and published in the following years.

Table 26: Physical properties of chlorine pentafluoride.

Property	SI Units	MKS Units	References
Melting point	$170 \pm 4\text{ K}$	$-103 \pm 4^\circ\text{C}$	[257]
Boiling point	259 K	-14°C	[257]
	260.2	-12.9°C	[255]
	254	-19°C	[256]
	259.4	-13.7°C	[248]

MKS = meter, kilogram, and second.

2.3.2.1 Density of Liquid Chlorine Pentafluoride

Early reports suggested that the density of liquid chlorine pentafluoride as a function of temperature can be expressed by the following equation [257]:

$$\rho_{\text{liq.}} = 2.696 - 3.08 \times 10^{-8} T$$

where $\rho_{\text{liq.}}$ is the density of liquid ClF_5 in g/cm^3 and T is the temperature in kelvin.

Table 27: Density of chlorine pentafluoride.

Temperature		Density, measured	Density, calculated
°C	K	g/cm^3	g/cm^3
-80.00	193.15	2.100	2.104
-57.00	216.15	2.036	2.030
-23.32	249.83	1.938	1.929
-23.00	250.15	1.922	1.928

Data source: [277]

Figure 20: Density of liquid chlorine pentafluoride, comparison of different data sources.

More accurate data are presented in Table 27. The experimental points in Table 27 over the temperature range of 193 to 372 K (−80 to +99 °C) were curve fitted by a least squares computer program and resulted in the following equation:

$$\rho_{\text{liq.}} = 3.553 - 1.396 \times 10^{-2}T + 4.565 \times 10^{-5}T^2 - 6.311 \times 10^{-8}T^3$$

where $\rho_{\text{liq.}}$ is the density of liquid ClF_5 in g/cm^3 and T is the temperature in kelvin. The standard error of estimate of this equation is $\pm 0.0059 \text{ g/cm}^3$. Figure 20 is a comparison of the two density equations. The scatter of data points at the high temperature end of the graph is obvious.

Figure 21, which is based on the same equation, but extends it to higher temperatures, shows a steep drop of density as the temperature approaches the critical point.

2.3.2.2 Velocity of Sound in Liquid Chlorine Pentafluoride

Data from experimental sonic velocity measurements in saturated liquid ClF_5 from 196 to 341 K (−77.1 to +68.7 °C) were curve fitted and resulted in the following equation [248]:

$$c = 1755 + 4.074T + 5.936 \times 10^{-4}T^2$$

where c is the velocity of sound in m/s and T is the temperature in kelvin. A graph derived from this equation is shown in Figure 22.

Figure 21: Density of liquid chlorine pentafluoride. (Reproduced and modified from [248].)

Figure 22: Velocity of sound in liquid chlorine pentafluoride. (Reproduced and modified from [248].)

The velocity of sound in liquid ClF_5 was measured over a range of pressures from saturation pressure at the prevailing temperature up to 6.8 MPa (1000 psia) for five different temperatures [66]. The velocity of sound data are tabulated in Table 28. The velocity of sound increased with pressure and decreased with temperature.

Table 28: Velocity of sound in liquid chlorine pentafluoride.

Temperature		Pressure		Velocity of sound	
K	°C	MPa	psia	m/s	ft/s
258.37	-14.78		Saturation	742.0	2434.4
258.37	-14.78	3.45	500	755.8	2479.7
258.37	-14.78	5.52	800	765.6	2511.8

2.3.2.3 Compressibility Coefficient of Liquid Chlorine Pentafluoride

The adiabatic compressibility of liquid ClF₅ was calculated from experimental sonic velocity and density data on the saturated liquid and can be expressed by the following equation [278], as referenced in [279]:

$$\beta_{\text{adiab}} = 1.1565 \times 10^{-4} + 1.3942 \times 10^{-6} T + 1.2708 \times 10^{-8} T^2 + 1.4680 \times 10^{-10} T^3 + 9.6855 \times 10^{-13} T^4$$

where β_{adiab} is the adiabatic compressibility in atm⁻¹ and T is the temperature in kelvin. The resulting curve is shown in Figure 23.

Figure 24 gives the isothermal compressibility of liquid chlorine pentafluoride. This curve is the result of curve-fitting the data from -40 to +30 °C and the equation is

$$\beta_{\text{isoth}} = 2.091 \times 10^{-4} + 3.712 \times 10^{-6} t + 4.238 \times 10^{-8} t^2 + 4.287 \times 10^{-10} t^3 + 2.973 \times 10^{-12} t^4$$

where β_{isoth} is the isothermal compressibility in atm⁻¹ and t is the temperature in °C.

Figure 23: Adiabatic compressibility of liquid chlorine pentafluoride. (Reproduced and modified from [248].)

Figure 24: Isothermal compressibility of liquid chlorine pentafluoride. (Reproduced and modified from [248].)

2.3.2.4 Vapor Pressure of Chlorine Pentafluoride

The vapor pressure curve of chlorine pentafluoride can be calculated from the following equation [257]:

$$\log p_v = 7.2683 - (1137.16/T)$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin. Another source gave a slightly different equation [255]:

$$\log p_v = 7.71 - (1257/T)$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin.

A third vapor pressure equation was given as [277, 279]:

$$\log p_v = 4.6029 - (1197/T)$$

where p_v is the vapor pressure in atm and T is the temperature in kelvin. Figure 25 is a comparison of vapor pressure data from two different sources, and Figure 26 uses this equation over a very wide range of temperatures.

Figure 25: Vapor pressure of chlorine pentafluoride – comparison of data from two different sources.

Vapor pressure data for chlorine pentafluoride over a very wide range, all the way from 228 to the critical point at 416 K (–45 °C to the critical point at +143 °C), are shown in Figure 26, which is on a semilogarithmic scale. Note that data read from the left curve need to be multiplied times 0.1, whereas data read from the right curve can be multiplied times 1.0.

Figure 26: Vapor pressure of chlorine pentafluoride. (Reproduced and modified from [248].)

2.3.2.5 Critical Point of Chlorine Pentafluoride

Critical point data for chlorine pentafluoride are listed in Table 29.

Table 29: Critical point data for chlorine pentafluoride.

Property	SI Units	MKS Units	Reference
Critical temperature	415.7 ± 1 K	142.6 ± 1 °C	[277]
Critical pressure	5242 ± 70 kPa	51.9 ± 0.7 atm	[277]
Critical density	0.565 ± 0.008 kg/m ³	0.565 ± 0.008 g/cm ³	[277]

2.3.2.6 Viscosity of Liquid Chlorine Pentafluoride

The viscosity of saturated liquid ClF₅ under its own vapor pressure can be described by the following equation, which was obtained for the temperature range 183 to 293 K (−90 to +20 °C) [279]:

$$\log \eta = -1.62875 + 335.636/T$$

where η is the viscosity in cPs and T is the temperature in kelvin. The curve for this equation is shown in Figure 27.

Figure 27: Viscosity of saturated chlorine pentafluoride. (Reproduced and modified from [248].)

Single data points of viscosity reported for saturated liquid ClF₅ under its own vapor pressure are summarized in Table 30.

Table 30: Viscosity of liquid chlorine pentafluoride.

Temperature			Kinematic viscosity		Absolute viscosity	
K	°F	°C	mm ² /s	cSt	mPa s	cPs
297	75	24	0.182	0.182	0.323	0.323
311	100	38	0.164	0.164	0.281	0.281
324	124	51	0.151	0.151	0.252	0.252
341	154	68	0.134	0.134	0.215	0.215
353	176	80	0.121	0.121	0.185	0.185

Data source: [66]

2.3.2.7 Surface Tension of Chlorine Pentafluoride

The surface tension of ClF_5 , which was experimentally determined over a temperature range from 223 to 298 K (-50 to $+25^\circ\text{C}$) is shown in Figure 28. The equation representing these data is

$$\sigma = 57.949 - 0.14463T$$

where σ is the surface tension in dyn/cm and T is the temperature in kelvin.

Figure 28: Surface tension of saturated chlorine pentafluoride. (Reproduced and modified from [248].)

2.3.2.8 Solubility/Miscibility of Liquid Chlorine Pentafluoride

In studying the miscibility of ClF_5 with other liquid non-metallic fluorides, the questions were whether these are simple physical mixtures, whether adducts form in specific stoichiometric ratios, or whether the two compounds might even chemically react to form new fluoride compounds, as is the case when reacting ClF_5 with Lewis acids. Fluorides studied as solvents or reaction partners for ClF_5 included ClF_3 , IF_5 , BrF_5 , SbF_5 , and BF_3 .

Binary and ternary mixtures of ClF_5 with a wide range of other fluorides (ClF_3 , BrF_5 , FClO_3 , XeF_2 , XeF_4 , OF_2 , N_2F_4 , ONF_3 , N_2O_4 , $\text{C}(\text{NO}_2)_4$, or $\text{C}(\text{NF}_2)_4$) were described in the ClF_5 Handbook [280]. A 3-to-1 mixture of ClF_5 with HNF_2 detonated within 1 min after mixing at 153 K (-120°C). However, it was also noted that very pure ClF_5 and HNF_2 reacted smoothly at 193 K (-80°C) to form ClNF_2 in good yields. ClF_5 reacts with N_2O_4 and is incompatible with N_2F_4 in the long term. See also [41].

In the binary $\text{ClF}_5/\text{ClF}_3$ system, an adduct $2\text{ClF}_5 \cdot 3\text{ClF}_3$ is formed at 40 mol % ClF_5 [281]. Separated layer formation in the liquid state and phase transitions of pure ClF_5 and the adduct compound were observed by thermal analysis. A peak at 183 K (-90°C) on the heating curve of ClF_5 corresponded to its melting point. At 168 K (-105°C) a phase transition of ClF_5 took place leading to its polymorphous transformation. The binary $\text{ClF}_5/\text{ClF}_3$ system had only limited miscibility. There is a miscibility gap and a bottom layer formed at 63–87 mol % ClF_5 (Figure 29).

Figure 29: Phase diagram of the $\text{ClF}_5/\text{ClF}_3$ system. (Reproduced and modified from [281].)

Differential thermal analysis (DTA) measurements indicated that the ClF_5/IF_5 system has a degenerate eutectic near 100% ClF_5 and 205 K (-68°C). The phase transition $\beta\text{-ClF}_5 \rightleftharpoons \alpha\text{-ClF}_5$ occurred at 168 K (-105°C) [282].

A DTA study showed that no compounds were formed between BF_3 and either ClF_5 or BrF_5 [283]. The BrF_5/BF_3 system contained a degenerate eutectic at 145 K (-128°) near the BF_3 side of the phase diagram. The ClF_5/BF_3 system exhibited mutual insolubility of the components in both liquid and solid states.

Mixtures of ClF_5 with FClO_3 were found to be completely miscible, compatible and insensitive to shock. The vapor pressures of various mixtures had a slight positive deviation from ideality over a temperature range of 227 to 293 K (-46 to $+20^\circ\text{C}$), but very little vapor pressure deviation was noted in an 80/20 $\text{ClF}_5/\text{FClO}_3$ mixture from 250 to 198 K (-23 to $+25^\circ\text{C}$). Mixtures of 14–40% ClF_5 with FClO_3 have been patented as oxidizers in storable propellant missiles [284]. Thus, a mixture of 39% ClF_5 and 61% ClO_3F has a freezing point of 183 K (-90°C).

$\text{ClF}_5/\text{N}_2\text{F}_4$ mixtures have been extensively studied by Aerojet, Reaction Motors, and Rocketdyne [285, 286] as a primary candidate high-energy storable hypergolic oxidizer formulation. Early studies indicated unwanted reaction between the two compounds above ambient temperatures. Additional laboratory investigations confirmed decomposition of the compounds in various materials over a wide temperature range and suggested that decomposition was both homogeneous and heterogeneous in nature [279]. Addition of 2.5% ClF_5 to N_2F_4 renders the latter hypergolic with hydrazine [287].

It is possible to form completely miscible mixtures of OF_2 and ClF_5 in amounts of approximately 84% by volume OF_2 , 16% ClF_5 , but only at intermediate temperatures above 184.6 K (-78.5°C) [288]. Even a small amount of 16% ClF_5 renders the otherwise unreactive OF_2 hypergolic with most fuels.

2.3.2.9 Solubility of Pressurant Gases in Liquid Chlorine Pentafluoride

Preliminary measurements of the solubility of gaseous nitrogen in liquid ClF_5 indicated a solubility of $\sim 3.0 \times 10^{-5} \text{ gN}_2/\text{gClF}_5 \text{ psi}^{-1}$ at 322 K (120°F ; [289]).

Additional later measurements at three different temperatures (Table 31) showed the solubility of nitrogen in liquid ClF_5 to be about 25% below the earlier measured solubility [66].

Table 31: Solubility of nitrogen gas in liquid chlorine pentafluoride.

Temperature		Vapor pressure		Pressure range		Solubility
K	$^\circ\text{F}$	MPa	psia	MPa	psia	lb N_2 (lb ClF_5) $^{-1}$ psi $^{-1}$
305	90	0.496	72	2.21 to 3.24	320 to 470	1.83×10^{-5}
322	120	0.793	115	4.00 to 4.27	580 to 620	2.25×10^{-5}
339	150	1.21	176	5.10 to 5.38	740 to 780	2.60×10^{-5}

Data source: [66]

The solubilities of oxygen and nitrogen in liquid ClF_5 were determined at 293 K (20°C) and (5×10^5) to (1×10^7) Pa and are listed in Table 32 [290]. Henry's law constants of nitrogen were pressure dependent, but Henry's law constants for oxygen were independent of pressure (Figure 30). The solubilities were relatively high and the oxygen solubility exceeded that in 25 other fluorine-containing organic solvents. The maxi-

Table 32: Solubility of nitrogen and oxygen in liquid chlorine pentachloride under pressure.

Nitrogen		Oxygen	
Pressure, Pa $\times 10^{-5}$	Solubility, vol.-%	Pressure, Pa $\times 10^{-5}$	Solubility, vol.-%
4.9	1.62	20.6	3.84
11.3	2.40	40.3	7.95
22.6	4.41	60.0	10.85
37.2	5.91	79.5	15.40
59.8	7.80	99.0	17.10
79.5	12.40	—	—
88.8	11.80	—	—

Data source: [290]

Note: The table heading in the original publication lists ClF₃(instead of ClF₅), but that is assumed to be a typographic error

Figure 30: Henry's law constants of solubility of nitrogen and oxygen in chlorine pentafluoride. (Reproduced and modified from [290].)

imum solubilities occurred at much lower pressures than one would expect in relation to the critical temperature of ClF₅ (430.6 K = 157.5 °C).

Helium, nitrogen, argon, or oxygen can be used as the pressurant gas for ClF₅ propellant tanks. Some of the oxygen dissolves in ClF₅ [291].

The solubility of helium in liquid ClF₅ is 117 ppm at 305 K, 2068 kPa or 126 ppm at 283.2K, 2068 kPa. The solubility of helium in liquid ClF₅ is illustrated in Figure 31.

Figure 31: Solubility of helium in liquid ClF₅. (Reproduced and modified from [292].)

The solubility of nitrogen in liquid ClF₅ is illustrated in Figure 32. The solubility of GN₂ in ClF₅ at 283.2 K and 2068 kPa is 2.96×10^{-2} mol/mol. Other sources suggest a solubility of GN₂ in ClF₅ of 0.433×10^{-2} lb/lb at 305 K and 2068 kPa.

Figure 32: Solubility of nitrogen in liquid ClF₅. (Reproduced and modified from [292].)

2.3.2.10 Thermal Conductivity of Liquid Chlorine Pentafluoride

It was very difficult to measure thermal conductivity and heat transfer properties of a highly reactive fluid such as chlorine pentafluoride. In many cases the equipment and thermocouples were coated with films of metal fluorides, which impeded the flow of heat.

Thermal conductivity measurements were conducted at Rocketdyne on propellant-grade (assay >99.0%) ClF_5 at 293, 313, and 353 K (20, 40, and 80 °C) using the concentric cylinder steady-state thermal conductivity cell [65]. Initial conductivity measurements were made using the concentric cylinder steady-state thermal conductivity cell at 293 K (20 °C) using four different temperature gradients (ranging from 0.18 to 0.58 °C = 0.331 to 1.057 °F) across the cell annulus. The thermal conductivity values obtained ranged from 7.9×10^{-2} to $8.5 \times 10^{-2} \text{ W m}^{-1} \text{ h}^{-1}$ (4.58×10^{-2} to $4.92 \times 10^{-2} \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1}$), with an average value of $8.2 \times 10^{-2} \text{ W m}^{-1} \text{ h}^{-1}$ ($4.72 \times 10^{-2} \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1}$). This value was considerably lower than the $0.105 \text{ W m}^{-1} \text{ h}^{-1}$ ($6.08 \times 10^{-2} \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1}$) obtained in previous measurements (using the same apparatus) under Contract AF04(611)-11407. During subsequent measurements at 40 °C (104 °F), the data varied from 5.4×10^{-2} to $6.9 \times 10^{-2} \text{ W m}^{-1} \text{ h}^{-1}$ (3.13×10^{-2} to $4.0 \times 10^{-2} \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1}$); a general downward drift in conductivity was noted from measurement to measurement, due to either decomposition of the sample or degradation of the surface of the apparatus. Thermal conductivity measurements were then conducted on saturated liquid ClF_5 using the “hot-wire” apparatus instead. The measurements, which covered the temperature range 237.8 to 327.7 K (−31.7 to +130.2 °F = −35.4 to +54.6 °C), were hindered in the upper temperature regions by the immediate onset of free convection in the ClF_5 and apparent reaction of the oxidizer with the platinum wire. The experimental data were curve-fitted by a least-squares computer program with the following expressions:

$$\lambda = 3.803 \times 10^{-4} + 1.00 \times 10^{-6}t$$

where λ is the thermal conductivity in $\text{cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1}$ and t is the temperature in °C. Later reviewers reported the thermal conductivity of liquid ClF_5 as $0.170 \text{ W m}^{-1} \text{ K}^{-1}$ at 298 K ($0.0981 \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1}$) or $0.191 \text{ W m}^{-1} \text{ K}^{-1}$ at 298 K ($0.456 \times 10^{-3} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1}$). The thermal conductivity of liquid ClF_5 is illustrated in Figure 33. There appears to be a contradiction in the temperature dependence of the thermal conductivity between theoretical predictions and actual experimental measurements. Although the thermal conductivity of **saturated** liquid ClF_5 calculated from equation

$$\lambda = 8.766 \times 10^{-2} + 1.35 \times 10^{-4}t$$

(where λ is the thermal conductivity in $\text{BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1}$ and t is the temperature in °F) and illustrated in Figure 33 is shown to increase with temperature, the thermal conductivity of liquid ClF_5 from a Weber equation predicted that thermal conductivity would be decreasing with temperature. The Weber equation is a correlation of thermal conductivity, density, molecular mass, and heat capacity. However, measurements

Figure 33: Thermal conductivity of saturated liquid ClF_5 . (Graph created by Schmidt 2018, based on data from [65].)

have shown the opposite to be the case, and thermal conductivity increased with temperature.

2.3.2.11 Heat Transfer Properties of Liquid Chlorine Pentafluoride

Testing with ClF_5 flowing in electrically heated tubes at subcritical and supercritical pressures was done and values of density, specific heat, thermal conductivity, and viscosity were established from existing data for pressures up to 34.5 MPa (5000 psia) and temperatures up to 978 K (1300 °F), and were presented in graphical form. In the course of determining the forced convection heat transfer characteristics of liquid ClF_5 in Monel K-500 tubes, 3 out of 22 tests were terminated by tube burnouts [293, 294]. In two of these tests, wall temperature measurements were available essentially at the time of tube burnout, whereas in the other case, the temperature measurement was lost shortly before burnout. During three initial tests, the results indicated that, although the critical heat flux limits of ClF_5 are relatively low, they were somewhat higher than expected.

2.3.2.12 Thermodynamic Properties of Chlorine Pentafluoride

The thermodynamic properties of chlorine pentafluoride are summarized in Table 33.

Table 33: Thermodynamic properties of chlorine pentafluoride.

Property	SI Units	MKS Units	Source	References
Heat of evaporation (ΔH) _{evap}	24.0 kJ/mol	5.74 kcal/mol	Gatti 1965	[255]
Heat of evaporation at normal boiling point (ΔH) _{evap}	22.92 kJ/mol	5.477 kcal/mol	Rogers et al. 1968	[277]

	–253 kJ/mol	–60.5 kcal/mol		

The molecular mass of ClF₅ is 130.44 g/mol

Heat Capacity of Liquid Chlorine Pentafluoride

The heat capacity of liquid ClF₅ can be expressed by the following polynomial equation [279]:

$$c_p = 1.0847 - 0.9522 \times 10^{-2}T + 0.3595 \times 10^{-4}T^2 - 0.4309 \times 10^{-7}T^3$$

where c_p is the heat capacity in cal g^{–1} °C^{–1} and T is the temperature in kelvin. The results from this equation are illustrated in Figure 34.

The heat capacity of liquid ClF₅ was measured over the temperature range 198 to 241 K (–75 to –32 °C) [297]. The value at 242 K (–31 °C) was 0.283 cal g^{–1} °C^{–1} and was approximately 10% lower than a value reported by Rocketdyne but is higher than the data in Figure 34. The molar heat capacity of gaseous ClF₅ can be calculated from the following equation [40]:

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + E/\tau^2$$

where C_p° is the molar heat capacity in J mol^{–1} K^{–1} and τ is the temperature in kelvin divided by 1000: $\tau = T/1000$ and A, B, C, D, and E are constants listed in Table 34 for two different temperature ranges.

Figure 34: Heat capacity of liquid chlorine pentafluoride (Graph created by Schmidt 2018, based on data from [279].)

Table 34: Coefficients for heat capacity, enthalpy of formation, and entropy of gaseous chlorine pentafluoride.

Temperature, K	298–1000	1000–6000
A	89.15560	132.7721

G	379.8566	450.3658
H	−238.4884	−238.4884

Data source: [40]

Enthalpy of Formation of Gaseous Chlorine Pentafluoride

The enthalpy of formation of gaseous chlorine pentafluoride can be calculated from the following equation:

$$H^{\circ} - H^{\circ}_{298.15} = A\tau + B\tau^2/2 + C\tau^3/3 + D\tau^4/4 - E/\tau + F - H$$

where $H^\circ - H^\circ_{298.15}$ is the excess heat of formation in kJ/mol and τ is the temperature in kelvin divided by 1000: $\tau = T/1000$ and A, B, C, D, E, and H are the constants listed in Tables 2–37 for two different temperature ranges. The standard enthalpy of formation of ClF_5 gas at 1 bar is $\Delta H_f^\circ \text{gas} = -238.49 \text{ kJ/mol}$.

Enthalpy of Formation of Liquid Chlorine Pentafluoride

The enthalpy of formation of liquid chlorine pentafluoride was determined by two independent sets of experiments [295]: In one experiment, the compound was reacted with hydrogen and in the other with ammonia in a calorimetric bomb. At the conditions of reaction, ClF_5 has a vapor pressure of 4.17 atm. The heat of vaporization of ClF_5 is $\Delta H_{\text{evap}} = 20.5 \text{ kJ/mol} = 4.9 \text{ kcal/mol}$ at $301 \text{ K} = 28^\circ\text{C}$. From the measured enthalpies of reaction and the known enthalpies of formation of products and reactants, corrected to their standard states, the standard enthalpy of formation of liquid ClF_5 was derived. The enthalpy of formation calculated on the basis of the hydrogen reaction was $\Delta H_f = -277.8 \pm 28.9 \text{ kJ/mol} = -66.4 \pm 6.9 \text{ kcal/mol}$. Calculated on the basis of the ammonia reaction, it was $\Delta H_f = -250.6 \pm 16.3 \text{ kJ/mol} = -59.9 \pm 3.9 \text{ kcal}$. Assuming that one questionable hydrogen run was invalid, the enthalpy of formation calculated as the average of the data from both sets of experiments was $\Delta H_f = -254.8 \pm 18.8 \text{ kJ/mol} = -60.9 \pm 4.5 \text{ kcal/mol}$.

The heat of reaction due to combustion of ClF_3 or ClF_5 in hydrogen gas was measured in a bomb calorimeter in order to determine the enthalpies of formation of these halides [298]. That of ClF_3 , already fairly well known, was used to standardize the apparatus for measurement concerning ClF_5 , for which no direct data had been available at that time.

The available data on the vibrational and rotational spectra of chlorine, bromine, and iodine pentafluorides have been used to calculate their ideal gas thermodynamic functions, C_p° , $(H^\circ - H^\circ_0)/T$, $(G^\circ - H^\circ_0)/T$, S° , ΔH_f° , ΔG_f° , and $\log K_f$ at 1 atm pressure [299]. For gaseous ClF_5 , a value of 237.2 kJ/mol (-56.7 kcal/mol) has been selected from the literature for the enthalpy of formation at 298.15 K and compared with the calculated data. The enthalpy of vaporization of ClF_5 at 298.15 K was calculated to be 20.9 kJ/mol (5.0 kcal/mol).

Entropy of Gaseous Chlorine Pentafluoride

The standard entropy of gaseous chlorine pentafluoride can be calculated from the following equation:

$$S^\circ = A \ln(\tau) + B\tau + C\tau^2/2 + D\tau^3/3 - E/(2\tau^2) + G$$

where S° is the standard entropy in $\text{J mol}^{-1} \text{ K}^{-1}$ and τ is the temperature in kelvin divided by 1000: $\tau = T/1000$ and A, B, C, D, E, and G are the constants listed in Tables 2–37 for two different temperature ranges. The standard entropy of ClF_5 gas at 1 bar is $310.73 \text{ J mol}^{-1} \text{ K}^{-1}$.

2.3.2.13 Spectroscopic Data for Chlorine Pentafluoride

Infrared Spectra of Chlorine Pentafluoride

The infrared and Raman spectra of XeOF_4 , IF_5 , BrF_5 , and ClF_5 have been recorded and compared and assignments of the fundamental vibration and combination frequencies made on the basis of a square-pyramidal structure for these molecules [300]. Valence force constants, based on estimated molecular parameters, have been calculated for these molecules. Comparisons between the different members of the series showed that the bonding in XeOF_4 was remarkably similar to that in the interhalogen compounds. A square-pyramidal structure of symmetry C_{4v} was assigned to ClF_5 by comparison with the spectra of BrF_5 , IF_5 , and XeOF_4 .

The IR spectrum of gaseous ClF_5 showed eight bands, a very strong one at 732 cm^{-1} , a strong one at 786 cm^{-1} , and four weak ones at 980 , 1216 , 1272 , and 1447 cm^{-1} (Figure 35) [255].

Figure 35: Infrared spectrum of gaseous chlorine pentafluoride. (Republished and modified from [255], with permission of © 1965 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

The IR spectra of solid ClF_5 have been recorded in argon and nitrogen matrices [301]. The previously suggested and very unusual triple coincidence of two deformational and one stretching mode at about 480 cm^{-1} have been experimentally confirmed. The observed $^{35}\text{Cl}/^{37}\text{Cl}$ isotope splitting permitted assignment of the bands to the individual modes of vibration. Spectroscopic evidence was presented for association of ClF_5 in the pure solid and in an Ar matrix at low dilution ratios. Figure 36 shows the infrared spectra of pure ClF_5 in a matrix at different concentrations recorded at 77 K .

Similar spectra are available for frozen ClF_5 at 4 K. In addition to $\nu_7(\text{E})$ at $726/713\text{ cm}^{-1}$, $\nu_3(\text{A}_1)$ at $493/483\text{ cm}^{-1}$, and $\nu_8(\text{E})$ at $482/479\text{ cm}^{-1}$, the following fundamentals were observed in good agreement with the previously published spectrum: $\nu_2(\text{A}_1)$ at 539 cm^{-1} and $\nu_9(\text{E})$ at 299 cm^{-1} .

Figure 36: Infrared spectrum of solid ClF_5 at 77 K. (Reprinted and modified from [301], with permission from © 1971 Elsevier; permission conveyed through Copyright Clearance Center Inc.)

The matrix IR and the gas phase Raman spectra of ClF_5 were recorded and all basic vibration frequencies, their isotopic shifts and relative intensities were determined [302]. A semiempirical CNDO/2 calculation of the dipole moment function of ClF_5 was used for analysis of the IR intensities and a comparison with measured data. The wave numbers of IR and Raman lines of ClF_5 as a solid in an Ar matrix, as a liquid, and in the gas phase with their vibration assignments are summarized in Table 35.

The left part of Table 35 contains the frequencies and relative intensities of the IR bands of ClF_3 in an Ar matrix. The band frequencies for the gas phase from Begun and Fletcher 1965 are given for comparison. Isotopic splitting is not observed in the gas phase, and the bands are assigned to the ^{35}Cl isotope, whose natural concentration exceeds that of ^{37}Cl by approximately a factor of two. The vibrations ν_3 , ν_8 , and ν_1 , ν_7 correspond to two pairs of close-lying lines, which cannot be separated in the gas phase, but are well resolved in the matrix. The IR spectrum of ClF_5 in the Ar matrix is similar to that obtained by Christie [301], but was taken with higher resolution. Figure 37 shows a portion of the ClF_5/Ar spectrum in the region of the ν_3 and ν_8 vibrations.

Table 35: Infrared and Raman spectra and vibration assignments of chlorine pentafluoride.

Vibration	IR spectrum		Raman spectrum		
	In Ar matrix	Gas phase ^a	Gas phase	Liquid phase ^b	
ν_1	³⁵ Cl 718.7 (6)	723 (35)	709 (30)		
ν_1	³⁷ Cl	714.2			
ν_2	³⁵ Cl	539 (0.1)	541	545 (12)	538 (10)
ν_3	³⁵ Cl	483.8 (3)	486	487 (100)	480 (100)
ν_3	³⁷ Cl	480.3			
ν_4			498 (30)		
ν_5			317 (0+)		
ν_6			385 (0.5)	375 (10)	
ν_7	³⁵ Cl	725.4 (100)	732	730 (9)	
ν_7	³⁷ Cl	712.7			
ν_8	³⁵ Cl	495.7 (0.7)			
ν_9	³⁵ Cl	299 (0.3)	302	300 (0+)	296 (0+)

^a source: [300]^b Numbers (in parentheses) indicate relative intensity of the spectral bands

Data source: [302]

Figure 38 shows the overlapping bands belonging to the ν_7 and ν_1 vibrations of both isotopic molecules together with their separate contours. It is interesting to note the doublet structure of the ν_7 band, which has a matrix origin.

The IR spectra of ClF₅ were studied in the gas phase and in solutions in liquid Kr ($T=130\text{ K}$) and Xe ($T=180\text{ K}$) under pressure over a wide frequency range (2500–200 cm⁻¹), including the third-order transition region [303]. The frequencies of >50 vibrational bands were measured and identified. The integral absorption coefficient of the $\nu_7(\text{E})$ band of ³⁵ClF₅ was determined in addition to the relative intensities of all observed ClF₅ bands, anharmonicity constants of some vibrations, and isotopic shifts for a series of bands. The different nature of the Cl–F_{axial} and Cl–F_{equatorial} bonds becomes distinct when looking at the IR spectra of ClF₅.

Accidental releases of XF₃ and XF₅ (X=Cl or Br) from industrial operations may be regarded as being among the most dangerous components in the hazardous emissions from electronic or nuclear material manufactures. The Cl and Br fluorides interact quickly with atmospheric moisture resulting in the formation of hydrogen halide, Cl and Br oxyfluorides and oxides, which are transformed into stable adducts (HHal)_x⋯(H₂O)_y, where Hal equals F, Cl, Br; $x+y \geq 2$. Vibrational spectra of the interhalogens were recorded as part of a study into reaction mechanisms with XF₃ and XF₅ compounds, their secondary hydrolysis products and the applicability of the remote laser sensing analytical techniques [304].

The infrared intensities (and wave numbers) for the fundamental vibrations of ClF₅, BrF₅, and IF₅ can be predicted by computational chemistry [305]. Comparison of the calculated intensities with the experimental spectra of XF₅ molecules revealed

Figure 37: Infrared spectrum of frozen ClF_5 in an argon matrix in the long wavelength range. (Republished and modified from [302], with permission of © 1986 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

that the predicted values were in fairly good agreement with the experimental values. The model and procedure allowed prediction of intensities of binary combination and overtone bands as well as fundamental vibrations.

Raman Spectra of Chlorine Pentafluoride

The Raman spectrum of RbClF_4 confirmed the square-planar structure (D_{4h} symmetry) of ClF_4^- in RbClF_4 [306]. Force constants for ClF_4^- indicated that the bonding in ClF_4^- is best described by the semiempirical molecular orbital model involving mainly two delocalized p -electron pairs of the Cl atom for the formation of two semi-ionic three-center four-electron p - σ bonds. A very unusual occurrence of two bending modes at a frequency higher than that of one of the stretching modes has been observed in the vibrational spectra of ClF_4^- and the approximate square-planar part of the ClF_5 molecule can be compared with ClF_4^- . The assignments of the vibrational modes and force constants reported by Begun, Fletcher, and Smith [300] for ClF_5 were confirmed.

Figure 38: Infrared spectrum of frozen ClF_5 in an argon matrix in the short wavelength range. (Republished and modified from [302], with permission of © 1986 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

Raman spectra of ClF_5 have been investigated in the condensed phases between room temperature and 4 K [307]. XRD and neutron diffraction patterns showed that the three solid phases previously described by NMR measurements are as follows. Solid I ($161\text{ K} < T < 181\text{ K}$), which is a body-centered cubic with $a = 5.7\text{ \AA}$, and its Raman spectrum were quite comparable with that of the liquid. Solid II ($117\text{ K} < T < 161\text{ K}$), which is orthorhombic with $a = 6.17\text{ \AA}$, $b = 7.22\text{ \AA}$, $c = 7.66\text{ \AA}$; according to the Raman spectra its structure seemed to be similar to that of solid BrF_5 . The structure of solid III ($T < 117\text{ K}$) had not been determined. However, the vibrational spectra showed that it was not very different from solid II. The structures of the tri- and pentafluorides of chlorine and bromine are very similar.

Raman spectra of ClF_5 were recorded in the condensed phases between room temperature and 4 K. The reorientation motions in the liquid phase (295 to 180 K) were deduced from Raman band shape analysis [308].

The Raman spectrum of ClF_5 in the gas phase is shown in Figure 39. The frequencies of the fundamental bands are given on the right-hand side of Table 35, where they are compared with frequencies for the liquid phase.

Ultraviolet/Visible Range Spectra of Chlorine Pentafluoride

The UV spectrum of ClF_5 is continuous. The absorption coefficients of ClF , ClF_3 , and ClF_5 were measured using a continuous spectrum source with a resolving power of 0.5 nm in the range from 160 to 300 nm [309]. The UV spectra of ClF_5 and several other halogen fluoride compounds are shown in Figure 40.

Microwave Spectra of Chlorine Pentafluoride

The rotational spectra of $^{35}\text{ClF}_5$ and $^{37}\text{ClF}_5$ were measured in the frequency range from 70 to 140 GHz and the molecular parameters (inertia, bond lengths) were calculated [311]. The $|K| = 2$ type splitting could be identified. A few years later, microwave spectra of ClF_5 were studied at frequencies up to 210 GHz and a new interpretation of the absorption lines gave better determination of the rotational parameters, the molecular structure, and force constants [312].

Several rotational transitions in the ground vibrational state of gaseous $^{35}\text{ClF}_5$ and $^{37}\text{ClF}_5$ were measured in the microwave spectrum [313]. From the frequency data the following constants were derived: $B_0(^{35}\text{ClF}_5) = 3550.272(4)$ MHz; $B_0(^{37}\text{ClF}_5) = 3545.885(4)$ MHz; $D_J = 0.76(9)$ kHz; $D_{JK} = -0.67(15)$ kHz; $eQq(^{35}\text{ClF}_5) = 43.93(8)$ MHz; $eQq(^{37}\text{ClF}_5) = 34.63(6)$ MHz; dipole moment $\mu = 0.586(10)$ D. The bond angle $\text{F}_{\text{axial}}-\text{Cl}-\text{F}_{\text{equatorial}}$ was estimated to be $86.5(1.0)^\circ$.

NMR Spectra of Chlorine Pentafluoride

^{19}F NMR spectra confirmed the tetragonal-pyramidal structure of ClF_5 , which was assumed on the basis of microwave spectra. ClF_5 spectra were found to be composed of a doublet with an intensity ratio 1:1 of hyperfine structure components in a strong field (F atoms at the base of the pyramid), and by a quintet with 1:2:4:2:1 in a weak field (F atom at the top of the pyramid) [314]. Chemical shifts of the doublet and quintet are -337 and 504 ppm, respectively, with a constant of spin-spin interaction of fluorine atoms at the J-level of 131 Hz. The absence of non-equivalent F atom exchange can be concluded from the temperature independence of component intensity and width in the temperature range from 183 to 293 K (-90 to $+20^\circ\text{C}$). A comparison with IF_5 and BrF_5 showed a decrease in F atoms' non-equivalency in going from Cl to I. For the

mixtures of ClF_3 (20 mass-%) and ClF_5 , no complex formation was observed, but the formation of complex compounds was concluded for solutions of ClF_5 (12.7, 16.5, and 25 mol %) in an excess of SbF_5 .

The high-resolution ^{19}F NMR spectrum of ClF_5 consisted of a doublet and quintet with relative intensities of 1:4 (an AB₄ system) [315]. This is consistent with a square pyramidal structure with four F atoms in the base and one non-equivalent F atom at the apex. The quintet was 170 ± 3 ppm downfield from the doublet, which was 280 ± 3 ppm upfield from trifluoroacetic acid (external standard). The coupling constant between the apical and base F atoms was 133 ± 3 Hz. For comparison, the internal chemical shifts for BrF_5 and IF_5 were also measured and found to be 130 ± 3 and 42 ± 3 ppm respectively. A study of the spectra in the temperature range from 183 to 293 K (–90 to +20 °C) showed little effect on line shapes, indicating an extremely slow exchange of the apical F. Temperature broadening was more apparent in BrF_5 and even greater in IF_5 , indicating that a self-ionization mechanism is involved in the exchange process.

Nuclear relaxation time measurements and interpretations of absorption line shape in ClF_5 and ClOF_3 provided molecular structure data for these compounds [316]. Thus, the chemical shift between non-equivalent fluorine atoms in ClOF_3 was equal to 50 ± 2 ppm. The coupling constant chlorine ^{35}Cl –fluorine was 192 Hz for the axial fluorine and less than 20 Hz for the equatorial fluorines. The mean coupling constant chlorine–fluorine in ClOF_3 and ClF_3 was obtained, in addition to other information, such as exchange times between fluorine atoms in ClOF_3 .

The ^{19}F NMR line shape and relaxation in solid ClF_5 were recorded from melting point down to liquid nitrogen temperature [317]. ^{19}F NMR and ^{35}Cl NMR and nuclear quadrupole resonance (NQR) together yielded information about phase transitions and molecular motions in ClF_5 . In particular, a new solid–solid transition was found at 117 K. ^{35}Cl wide-line and ^{19}F high-resolution NMR spectra were obtained in the high temperature phase S I, which turned out to be a plastic phase where molecular reorientations ($\tau_g = 8 \times 10^{-12}$ s) are nearly as fast as in the liquid. In addition to the reorientation, there was a much slower translational diffusion, the main characteristics of which were derived from ^{19}F T_1 and $T_{1\rho}$ measurements. In the low temperature phases S II and S III, the ^{19}F T_1 is due to rotations of the molecules by jumps around their C_4 axis ($\tau_r = 10^{-8}$ s at 110 K).

The ^{35}Cl nuclear quadrupole resonance frequency ν_q was studied as a function of temperature between 4.2 and 135 K [318]. No break was seen on either the $\nu_q(T)$ curve or its derivative, in spite of a phase change observed in the ^{19}F NMR at 117 K. The quadrupole coupling constant can be interpreted in terms of the occupancy of the 3p orbitals on Cl as predicted by MO calculations and compared with the value found by microwave spectroscopy. A value of the lowest libration frequency ($\nu \approx 30 \text{ cm}^{-1}$) was obtained, which was also consistent with the value of the relaxation time, T_1 , of ^{35}Cl nuclei.

A very detailed summary of nuclear relaxation and molecule motions in six different halogen fluorides was published in a French report [319]. The NMR and NQR spectra of solid phases of ClF_3 , BrF_3 , ClF_5 , BrF_5 , IF_3 , and IF_7 were recorded and compared. The relaxation times relate to molecular motion. The three solid phases of ClF_5 and the four solid phases of IF_7 were studied in detail. In both ClF_5 and IF_7 the high temperature phases are plastic phases. At low temperatures along with fast rotations about the molecule's axis a tilting of the axis occurs in ClF_5 and an intermolecular F-exchange was observed in IF_7 .

2.3.2.14 Molecular Structure of Chlorine Pentafluoride

Prior to the actual discovery of ClF_5 , chemists were already speculating about what molecular structure this molecule might have. Chlorine pentafluoride seems to possess the molecular structure of a quadratic bipyramid similar to that of BrF_5 and XeOF_4 (Figure 41).

Figure 41: Molecular structure of chlorine pentafluoride

Electron diffraction spectroscopy is an advanced method for identifying the crystalline structure of solid ClF_5 and the structure of the ClF_5 molecule [320]. Electron-diffraction measurements showed that the ClF_5 molecule has a tetragonal pyramid structure (C_{4v}) with the Cl atom and one F atom out of the 4 F-atom plane. The interatomic distances and angles can be determined by this method.

The dielectric constant of ClF_5 gas at 297 K is 1.00279 ± 0.00007 at 10 MHz. The dielectric constant as a function of temperature between 193 and 256 K (−80 and −17 °C) is

$$\epsilon = -0.015t + 3.08$$

where t is the temperature in °C.

Computational Chemistry: Illuminating the Molecular Structure of Chlorine Pentafluoride

Molecular orbital populations of atomic orbitals, and effective charges of atoms in ClF_5 obtained by an MO LCAO self-consistent field method showed that the bond in ClF_5 can be qualitatively described by one axial two-center bond, Cl–F, and by two equatorial

three-center bonds, F—Cl—F, with highly delocalized molecular orbitals [321]. With an increasing number of F atoms, the covalence character of the Cl—F bond increased with a considerable increase of the 3d-atomic orbital contribution.

2.3.2.15 Electrical Properties of Chlorine Pentafluoride

Electrical Conductivity of Chlorine Pentafluoride

The specific electric conductivity of liquid ClF₅ is below $1.3 \times 10^{-9} \text{ Ohm}^{-1} \text{ cm}^{-1}$ over the temperature range from 193 to 256 K (–80 to –17 °C) [277]. Another data point is $0.45 \times 10^{-9} \text{ Ohm}^{-1} \text{ cm}^{-1}$ at 256 K (–17 °C). The values of specific conductivity and dielectric constant of liquid ClF₅ are lower than those of ClF₃ at any given temperature.

Dielectric Constant of Chlorine Pentafluoride

The dielectric constant of liquid ClF₅ as a function of temperature in the temperature range 193–256 K (–80 to –17 °C) is a simple linear function

$$\varepsilon = 3.08 - 0.015t$$

where ε is the dielectric constant and t is the temperature in °C [277]. The dielectric constant of gaseous ClF₅ at room temperature was 1.00279 ± 0.00007 .

Dipole Moment of Chlorine Pentafluoride

Based on rotational transitions in the ground vibrational state of gaseous ³⁵ClF₅ and ³⁷ClF₅ the dipole moment was calculated to be $\mu = 0.586(10) \text{ D}$.

2.3.3 Chemical Properties of Chlorine Pentafluoride

Early observations already indicated that chlorine pentafluoride is not quite as aggressive an oxidizer as fluorine or chlorine trifluoride. This may be partially caused by the symmetry of the molecule. It is still sufficiently reactive to be hypergolic with most fuels, but not quite as corrosive when interacting with materials of construction.

2.3.3.1 Thermal Stability of Chlorine Pentafluoride

Based on theoretical considerations, chlorine pentafluoride should be as stable as xenon tetrafluoride. It appears that chlorine pentafluoride may decompose at elevated temperatures in reversal of its formation from chlorine trifluoride and fluorine. Such a decomposition would be very undesirable if it occurred during long-term storage in a propellant tank as the tank pressure could rise substantially to the point of tank rupture.

Depending on the conditions, the reaction

can proceed in either direction. The equilibrium, which allows the formation of ClF₅, also limits its thermal stability [270]. The progress of the reaction at temperatures be-

tween 484 and 544 K was monitored by measuring the pressure rise with time. The data were fitted to a van't Hoff equation in the form of $\ln K_p = (9175/T) - 21.30$, which gave a heat of reaction of -76.1 ± 3.8 kJ/mol (-18.2 ± 0.9 kcal/mol) and an entropy of reaction of 42.3 ± 1.8 e.u.

The homogeneous gas phase decomposition kinetics of chlorine pentafluoride were determined in the temperature range from 525 to 580 K (252–307°C) using an electrically heated, stirred flow reactor with a retention volume of 91 mL and made from Monel metal, and gave a dissociation energy of 154.8 kJ/mol (37 kcal/mol) [322]. The dissociation energy at 400 K was -77 kJ/mol (-18.5 kcal/mol). A least squares fit of the data to the Arrhenius equation gave

$$k_1 = 10^{13.02} \exp(-36800/RT) \text{ s}^{-1}$$

A non-chain radical mechanism appeared to be most likely. In a similar evaluation [38] Blauer et al. [111] concluded that the thermal dissociation of ClF_5 at elevated temperatures is well described by the statistical theory of unimolecular reaction rates. The activation energy of experimentally observed first-order dissociation in a shock tube was 196.6 ± 8 kJ/mol (47 ± 2 kcal/mol), in agreement with dissociation rate constants derived from statistical theory, but quite different from results in flow reactors or static reactors.

Other investigators made a study of the dissociation of ClF_5 in a flow reactor over the temperature range 525–581 K. The course of the reaction was monitored by means of IR spectroscopy. Empirically, it was found that the reaction is unimolecular and the rate constant was given as

$$k_1 = 10^{18} \exp(-36800/RT) \text{ s}^{-1}$$

The thermal dissociation of ClF_5 was investigated using two different techniques over the temperature range 520 to 1120 K [323]. At temperatures above 800 K the course of the reaction of 0.17–4.5% ClF_5 in argon occurring behind incident shock waves was followed by monitoring of the UV absorption of the reacting system at 2200 Å. ClF_5 has a very large extinction coefficient relative to those for F_2 and ClF at 2200 Å. Although ClF_3 also has a large extinction coefficient at this wavelength, its presence can be accounted for by a correction. The pressure exponent n had a value of 0.7 ± 0.2 . The resulting 1.7th order rate constant had the form

$$k_{11} = 10^{15.8} \exp(-41500 \pm 2500/RT) \text{ mL}^{0.7} \text{ mol}^{-0.7} \text{ s}^{-1}$$

or a first-order rate constant of

$$k_{10} = 0.16 \times 10^{14} \exp(-42403/RT) \text{ s}^{-1}.$$

At lower temperatures the study was conducted with static reactors, which were coupled to a mass spectrometer where the course of the dissociation at low temperatures

was followed by monitoring evolved F_2 at m/e 38 and ClF_4^+ at m/e 111. The rate constant for the static reactor was

$$k_d = 10^{16 \pm 1} \exp(-46300 \pm 2300/RT) \text{ s}^{-1}$$

The unimolecular decomposition rate constants were compared with predictions of a statistical theory. The statistical theory was found to give a good description of the data taken at elevated temperatures; however, it was at great variance with data taken from the static reactor. The difference was attributed to wall effects in the static reactor. The addition of large amounts of NO or ClF to the reacting mixture appeared to have no significant effect on the rate constant.

In a similar study using a 92-mL stirred flow reactor and measuring the disappearance of ClF_5 by measuring the change in its IR absorption at $12.5 \mu\text{m}$, the first-order rate constants obtained over the temperature range 525–580 K (252–307 °C) were expressed by the Arrhenius equation [324]:

$$k_1 = 10^{15.20} \exp(-43034/RT) \text{ s}^{-1}$$

2.3.3.2 Reactions of Chlorine Pentafluoride

Reactions of ClF_5 with several hundred inorganic and organic chemicals were tested and described in the ClF_5 Handbook [289].

Reactions of Chlorine Pentafluoride with Inorganic Compounds

The binary chlorine fluorides ClF, ClF_3 , and ClF_5 , when used in excess, all undergo facile fluorine–oxygen exchange reactions with the nitrate anion, forming $FClO_2$, unstable $FCIO$, and $ClONO_2$ respectively as the primary products [325]. Whereas $FCIO_3$ does not react with $LiNO_3$ at temperatures as high as 348 K (75 °C), $FCIO_2$ readily reacts with either $LiNO_3$ or N_2O_5 to give $ClONO_2$ and O_3 , probably via the formation of an unstable O_2ClONO_2 intermediate. With an excess of ClF, chlorine nitrate undergoes a slow reaction to give $FCNO_2$ and Cl_2O as the primary products, followed by Cl_2O reacting with ClF to give Cl_2 , ClF, and $FCIO_2$. The alkali–metal fluorides CsF, RbF, and KF catalyze the decomposition of ClF_5 to ClF_3 , and F_2 .

If using an oxygen source other than nitrate ion, the fluorine in ClF_5 can be gradually replaced by oxygen, forming chlorine oxide fluorides while maintaining the state of oxidation of the central chlorine atom. The reaction of potassium dinitramide $KN(NO_2)_2$ with ClF_5 leads to stepwise replacement of two fluorine ligands by a doubly bonded oxygen atom. Thus, $KN(NO_2)_2$ readily reacted with ClF_5 at 260 K (–13 °C) producing an equimolar mixture of $KClOF_4$ and $KClF_4$ [326]. The formation of $KClOF_4$ is remarkable because with most fluorine–oxygen exchange reagents, such as NO_3^- , the exchange process cannot be interrupted at the $ClOF_4$ stage and proceeds all the way to $FCIO_2$ as the only product.

The reaction of ClF_5 with N_2F_4 prevents the use of mixtures of these two very desirable oxidizers. The reaction

starts to take place at room temperature. It is not facilitated by the ClF_5 first decomposing into ClF_3 and F_2 , but proceeds directly. F_2 is not an intermediate in this reaction [324]. If this reaction proceeds via a direct bimolecular process, then the kinetic rate equation may be

$$k_2 = 10^{12.20} \exp(-25760/RT) \text{ L mol}^{-1} \text{ s}^{-1}$$

Thus, the half-life for a mixture containing 1 atm of N_2F_4 and 1 atm of ClF_5 at 344 K (71 °C) would be approximately 225 days.

Reactions of Chlorine Pentafluoride with Water

In the presence of an excess of ClF_5 and in the absence of catalytic metal, the hydrolysis of ClF_5 can go to an intermediate product of chloryl fluoride

but with an excess of water and in the presence of metals that catalyze the decomposition of FClO_2 , the products are ClO_2 , FClO_3 , and HF:

where one has to remember that ClO_2 is unstable, explosive, and extremely sensitive. The interaction of ClF_5 with water in anhydrous HF solutions was investigated by means of Raman spectroscopy [327]. The reaction between ClF_5 and H_2O yielded only one product (ClO_2F) regardless of the temperature of the process, quantity, and concentration of chemicals. ClOF_3 did not form during interaction of ClF_5 with hydroxides of the following metals: Ni, Mn, Al, and Si. The interaction in the system $\text{H}_3\text{OBF}_4/\text{HF}/\text{ClF}_5$ in the temperature range 293–273 K resulted in a practically quantitative yield of $[\text{ClOF}_2]^+[\text{BF}_4]^-$.

Dinitrogen tetroxide was found to be incompatible with ClF_5 , resulting in a pressure rise in excess of 2.41 MPa (350 psia) after 18 h when samples were mixed and stored in a closed container.

2.3.3.3 Lewis Addition Compound and Complex Salt Formation Reactions with Chlorine Pentafluoride

Chlorine pentafluoride forms stable salts with Lewis acids. These salts have been evaluated as potential solid gas generant oxidizers that would release fluorine or chlorine fluorides on ignition and thus constitute a convenient and safe method of storing fluorine or chlorine fluorides for later use in rocket propellants or lasers.

Chlorine mono-, tri-, and penta-fluoride are quite reactive. Of these, the first two compounds show amphoteric character and form ionic complexes with strong Lewis acids and bases. Thus, ClF forms with strong Lewis acids the FCl_2^+ cation [46], and with strong Lewis bases the ClF_2^- anion. Similarly, the ClF_2^+ cation and ClF_2^- anion have been prepared from ClF_3 . The reactions with ClF_5 were different [328]. ClF_5 and AsF_6 , when mixed at 195 K (-78°C), produced the 1:1 adduct $\text{ClF}_5 \cdot \text{AsF}_5$, a white, crystalline solid. A heat of formation of $[\text{ClF}_4]^+[\text{AsF}_6]^- (\text{S})$, $\Delta H_{298}^\text{f} = -1576 \text{ kJ/mol}$ (-376.8 kcal/mol) was calculated for this compound. The heat of dissociation obtained for $[\text{ClF}_4]^+[\text{AsF}_6]^- (\text{S})$ was 105.6 kJ/mol (25.23 kcal/mol). The 1:1 combining ratio was established by quantitative synthesis and IR measurements of the gas phase above the solid complex. The latter measurements showed that the complex was completely dissociated in the gas phase at 298 K (25°C). Similarly, ClF_5 and SbF_5 , when combined either under pressure or in HF solution, formed the 1:1 adduct. The tendency to form adducts with ClF_5 decreased in the order $\text{SbF}_5 > \text{AsF}_5 > \text{BF}_3$, and was the same as that observed for other halogen fluorides such as ClF_3 or ClF.

Tetrafluorochloronium(V), Hexafluorochloronium(VII), and Hexafluorochlorate(V) Complexes from Reactions of Chlorine Pentafluoride with Inorganic Compounds

In comparing the stability of the various fluoro-chlorine ions among themselves, and comparing it with that of tetrafluoroammonium salts, it is interesting to note that the two most promising energetic oxidizer cations are NF_4^+ and ClF_6^+ . Their central atoms are in their highest oxidation states (N^{+4} and Cl^{+7}) and they possess a high fluorine content. Although the N—F and Cl—F bond energies are relatively low, which make them powerful reactive oxidizers, these bond energies are high enough to give them good stability. Furthermore, these two ions possess outstanding kinetic stability owing to their energetically favorable structures (tetrahedron for NF_4^+ and octahedron for ClF_6^+). This is also reflected by the fact that NF_4^+ and ClF_6^+ are isoelectronic with CF_4 and SF_6 respectively, which are the two most thermally stable covalent inorganic fluorides.

ClF_6PtF_6 , which is useful as an oxidizer for rocket propellants and in the preparation of other oxidizing agents containing chlorine in the +7 valence state, can be prepared by reaction of PtF_6 and ClF_5 at 195–77 K (-78 to -196°C) under UV light in a sapphire reactor [329]. After condensation, the mixture was slowly heated to room temperature, exposed to UV light, and held under vacuum for 5–14 days at $<358 \text{ K}$ ($<85^\circ\text{C}$), during which time ClF_4PtF_6 , the condensation product in the absence of UV, which is formed in about equimolar proportions with ClF_6PtF_6 , decomposed, leaving a solid PtF_4 residue. For example, 1.26 mmol PtF_6 and 3.78 mmol ClF_5 were condensed at 77 K (-196°C) in a sapphire reactor under UV irradiation and the product held under vacuum and irradiation for 8 days at 295–296 K (22 – 23°) to give 0.489 g of a bright-yellow solid containing 81% ClF_6PtF_6 and 19% PtF_4 .

The identity of a stable species having an 890 cm^{-1} infrared absorption as ClF_6^+ was unambiguously established by ^{19}F NMR and vibrational spectroscopy [330]. The vibrational spectrum of ClF_6^+ was compared with that of isoelectronic SF_6 .

The vibrational spectra of $\text{ClF}_4^+\text{AsF}_6^-$, $\text{ClF}_4^+\text{SbF}_6^-$, and $\text{ClF}_4^+\text{PtF}_6^-$ were compared with those of the corresponding BrF_6^+ and IF_6^+ salts [331]. All fundamentals were assigned and a valence force field was computed for ClF_4^+ .

As the techniques that had successfully been used for the synthesis of NF_4^+ salts did not result in ClF_6^+ , other fluorinating agents were investigated. The ClF_6^+ cation was prepared in the form of its PtF_6^- salt from the reactions of PtF_6 with either FCIO_2 , or ClF_3 [332]. A displacement reaction between $\text{ClF}_6^+\text{PtF}_6^-$ and FNO at -78°C yielded only ClF_5 and F_2 , indicating that ClF_7 cannot exist under the given reaction conditions. Attempts were unsuccessful to prepare $\text{ClF}_6^+\text{BF}_4^-$ by low-temperature glow discharge of a $\text{ClF}_5/\text{F}_2/\text{BF}_3$ mixture, to prepare ClF_6^+ salts from ClF_5 , F_2 , and the Lewis acids SbF_5 , AsF_5 , or BF_3 at elevated temperatures and pressures, or to prepare ClF_6^+ salts either from ClF_3O and PtF_6 or from ClF_3O , F_2 , and SbF_5 . Iridium hexafluoride was found to be too weak an oxidizer to produce any heptavalent, chlorine-containing cations from FCIO_3 .

For a long time the only known ClF_6^+ salt was $\text{ClF}_6^+\text{PtF}_6^-$, which could be prepared only as an inseparable mixture with ClF_4PtF_6 . Using KrF_2 as the oxidizer, it was possible to prepare pure $\text{ClF}_6^+\text{AsF}_6^-$ and $\text{ClF}_6^+\text{SbF}_6^-$ [333]. The salts were thoroughly characterized and exhibited very good thermal stability.

In order to increase the energy content of ClF_6^+ salts, the weight of the non-energetic counter ion must be minimized. This goal was achieved by replacing AsF_6^- by BF_4^- using low-temperature metathetical techniques previously developed for NF_4^+ salts [334]. ClF_6BF_4 is a white crystalline solid that is highly soluble in anhydrous HF . It is stable at room temperature and starts to slowly decompose under a dynamic vacuum at about 343 K (70°C) according to

The nature of the decomposition products was established by their IR spectra, which showed only the absorptions characteristic for BF_3 and ClF_5 . The $\text{ClF}_6^+\text{BF}_4^-$ also exhibited good thermal stability and is a potentially useful oxidizer. Attempts to replace the non-energetic BF_4^- anions by the energetic ClO_4^- anion were only partially successful [335]. By analogy with NF_4ClO_4 [336], ClF_6ClO_4 was found to be thermally unstable. However, as with NF_4ClO_4 , the decomposition of ClF_6ClO_4 provided a new, high-yield synthesis of the interesting hypofluorite, FOClO_3 .

Salts of the composition $[\text{ClF}_6^+][\text{BiF}_6^-]\cdot\text{BiF}_5$ and $[\text{ClF}_6^+][\text{Bi}_2\text{F}_{11}^-]$ have been synthesized by high temperature and pressure fluorinations [337, 338]. The products have been characterized by elemental analysis and by comparison of IR, XRD, and NMR spectroscopic data, thermal stability and chemical reactivity behavior with those of the $[\text{ClF}_2^+][\text{BiF}_6^-]$ and $[\text{ClF}_4^+][\text{BiF}_6^-]$ salts.

The synthesis of hexafluorochloronium(VII) hexafluoroplatinate(V), $[\text{ClF}_6^+][\text{PtF}_6^-]$, from the reaction of ClF_5 and PtF_6 was described as an oxidation-reduction reaction. This has been confirmed by elemental analyses, IR and Raman spectroscopy, XRD, and displacement reaction with trifluorochlorine oxide [339]. This was the first example of a perfluorinated heptavalent chlorine cation. Based on preliminary XRD powder pattern, $[\text{ClF}_6^+][\text{PtF}_6^-]$ has a cubic structure.

Vibrational spectra have been recorded for the known adducts $\text{ClF}_5 \bullet \text{AsF}_5$, $\text{ClF}_5 \bullet x\text{SbF}_5$ ($x=1.08$ and 1.36), $\text{BrF}_5 \bullet 2\text{SbF}_5$, and $\text{IF}_5 \bullet \text{SbF}_5$. The spectra of the ClF_5 adduct were consistent with a predominantly ionic structure containing the ClF_4^+ cation [331].

The ClF_4^+ cation was prepared in the form of its PtF_6^- salt from the reactions of PtF_4 with either FCIO_2 or ClF_5 [332]. A displacement reaction between $\text{ClF}_4^+ \text{PtF}_6^-$ and FNO at 195 K (-78°C) yielded only ClF_5 and F_2 , indicating that ClF_7 cannot exist under the given reaction conditions. Attempts to prepare $\text{ClF}_4^+ \text{BF}_4^-$ by low-temperature glow discharge of a $\text{ClF}_5/\text{F}_2/\text{BF}_3$ mixture, to prepare ClF_6^+ salts from ClF_5 , F_2 , and the Lewis acids SbF_5 , AsF_5 , or BF_3 at elevated temperatures and pressures, or to prepare ClF_4O^+ salts either from ClF_2O and PtF_4 or from ClF_3O , F_2 , and SbF_5 were unsuccessful.

Salt formation in the $\text{ClF}_5/\text{SbF}_5$ system was studied by DTA for mixtures with 0–100% SbF_5 [340]. Three compounds, $\text{ClF}_5 \bullet \text{SbF}_5$, $\text{ClF}_5 \bullet 2\text{SbF}_5$, and $\text{ClF}_5 \bullet 4\text{SbF}_5$ were formed congruently with melting points of 393 , 337 , and 335 K (120 , 64 , and 62°C) respectively. These compounds probably consist of endless chains of ClF_4^+ and SbF_6^- , $\text{Sb}_2\text{F}_{11}^-$, or $\text{Sb}_4\text{F}_{21}^-$ ions connected by weak F^- bridges.

The ^{35}Cl , ^{75}As , and ^{181}Ta NQR spectra of $\text{ClF}_x \bullet n\text{SbF}_5$ ($x=3, 5$; $n=1, 2, 4$), $\text{ClF}_5 \bullet \text{TaF}_5$, $\text{ClF}_3 \bullet \text{MF}_5$ ($\text{M} = \text{As}, \text{Nb}, \text{Ta}$), ClF_5 , and CsClF_4 were measured [341]. Based on the ^{35}Cl NQR spectra, the acceptor capacity of anions decreased in the sequence $\text{Sb}_4\text{F}_{21}^- > \text{Sb}_2\text{F}_{11}^- > \text{AsF}_6^- > \text{SbF}_6^- > \text{NbF}_6^- > \text{TaF}_6^-$.

In extending the chemistry of high-fluorine content oxidizers to hypervalent, high-oxidation state fluorides of nitrogen, oxygen, and the halogens, typical target compounds were chlorine pentafluoride oxide, chlorine hexafluoride anion, nitrogen pentafluoride, nitrogen difluoride anion, and combinations of high oxidation state halogen fluoride anions with organic cations [342]. Special experimental techniques, such as low-temperature photolysis and glow-discharge, matrix-isolation spectroscopy, and microwave discharge reactions were explored for the syntheses of these species.

2.3.3.4 Reactions of Chlorine Pentafluoride with Organic Compounds

Chlorine pentafluoride will react hypergolically with most hydrogen-containing organic compounds. Only a few perfluorinated organic compounds are compatible with ClF_5 . Chlorine pentafluoride is compatible with and soluble in Cl_3CF or $\text{Cl}_2\text{FC}-\text{CClF}_2$ at room temperature [343]. If ^{19}F is dissolved in HF , no ^{19}F exchange takes place. Chloroform and carbon tetrachloride both react slowly with ClF_5 at room temperature to form Cl_2 and CFCl_3 . A preliminary experimental characterization of $\text{ClF}_5/\text{C}(\text{NO}_2)_4$

mixtures indicated compatibility between two compounds. Vapor pressure measurements at 271 and 293 K (0 and 20 °C) resulted in vapor pressures very near those of ideal, non-reacting mixtures.

In contrast to limited substitutive fluorination of aromatics with halogen fluorides such as ClF , ClF_3 , BrF_3 , or IF_5 , fluorination is the predominant reaction path with ClF_5 [344]. Under non-catalytic liquid phase conditions, benzene was converted to fluorobenzene (54% yield) and chlorobenzene (37% yield) respectively. One possible fluorination mechanism may involve a transition complex of ClF_5 with benzene. For a heterocyclic substrate, i.e. 2,4,6-trifluoropyrimidine, substitutive fluorination predominated over chlorination. Enhanced exchange fluorination of CCl_4 was effected with ClF_5 ($\text{CF}_2\text{Cl}_2 \gg \text{CFCl}_3 > \text{CF}_3\text{Cl}$) as compared with ClF_3 ($\text{CFCl}_3 \gg \text{CF}_2\text{Cl}_2$).

2.3.3.5 Analysis of Chlorine Pentafluoride

At the time when the USAF still procured ClF_5 for rocket applications, the ClF_5 that was supplied to the Air Force had to be in conformance with Military Specification MIL-P-27413 (tentative). This specification required a ClF_5 assay of at least 99.5 mass-% as determined by GC, and the maximum HF content as determined by IR was 0.2 mass-%.

Glass in a mass spectrometer inlet must be avoided because it creates spurious SiF_4 peaks and all glass in the inlet system of the original apparatus has been replaced with Monel and Teflon. Fluorine gas at 700 mm Hg was used to passivate the inlet manifold. Oxygen difluoride mass spectra displayed rhenium oxyfluorides as the result of sample corrosive interaction with a rhenium filament in the source. Mass spectrometric analysis of ClF_5 (Figure 42) showed that the two strongest peaks were $^{35}\text{ClF}_2^+$ and $^{35}\text{ClF}_4^+$ [345, 346]. There was no neutral $^{35}\text{ClF}_5$ peak. HF, SiF_4 , organofluoride, HBr,

Figure 42: Mass spectrum of chlorine pentafluoride. Ionization Voltage 50 eV. (Reproduced and modified from [346].)

BrF, and HCl were detected as contaminants in the as-received ClF₅. Mass spectra of BrF₅ were made in the same apparatus for comparison.

Low-temperature mass spectrometry of fluorine-containing compounds can be done with a cryogenic inlet system built for a mass spectrometer [347].

The ionization of molecular beams of ClF₅ was investigated by electron-impact mass spectrometry [348]. Appearance potentials and excess kinetic energy of the ions formed were measured. The lowest value of electron affinity of ClF₂ and ClF₃ and the upper limit of the ionization potential of the ClF₄ radical could be derived from these measurements.

2.3.4 Handling of Chlorine Pentafluoride

Detailed instructions on the safe handling of ClF₅ are contained in several of the ClF₅ handbooks and propellant manuals, including *The ClF₅ Handbook* [289]. The handling precautions are similar to those practiced with elemental fluorine or ClF₃. Pressurant gas that is vented from pressurized ClF₅ tanks at the end of a test contains large amounts of ClF₅ and must be passed through a scrubber with a caustic neutralizing solution or (in remote areas) it can be fed into a propane or natural gas torch where it is flared off in a flare stack high above ground (but the combustion products still contain toxic HF). Spill neutralization methods that were developed initially for chlorine trifluoride or liquid fluorine can be applied to ClF₅ spills as well [349].

2.3.5 Materials Compatibility with Chlorine Pentafluoride

A general summary of the results from ClF₅ materials compatibility studies indicated that the behavior of ClF₅ with various structural materials is generally similar to that of ClF₃. The same as with elemental fluorine or chlorine trifluoride, all materials that come in contact with ClF₅ need to be thoroughly cleaned and degreased. Then a slow passivation, initially with ClF₅ diluted with an inert gas, allows a protective passivating fluoride film to form on the metal. The *ClF₅ Handbook* (1966) [289] contains detailed summaries of materials that are compatible with ClF₅ and other materials that are incompatible and must be avoided.

2.3.5.1 Compatibility of Chlorine Pentafluoride with Metals

Most metals that form a protective passivating layer of insoluble fluorides are compatible with ClF₅. Notable exceptions in the metals tested are molybdenum and columbium (niobium), which undergo complete reaction. The compatibility of titanium with ClF₅ is still in doubt because of conflicting results in comparison with ClF₃. The presence of moisture may have a significant detrimental effect on the rate of film formation or corrosion of the metal. Of the metals tested under conditions of moisture contamination, only Hastelloy C and nickel 200 provided complete resistance to attack.

Transition metals (Cr, Mn, Co, Ni, Pd, Pt, Cu, Zn, and Cd), which are least reactive with ClF_5 in studies to 423 K (150 °C), all form fluorides with melting points above 1123 K (850 °C).

Impact sensitivity tests were run on Al2014-T6, 347 stainless steel, nickel 200, and magnesium AZ31B in liquid ClF_5 at 303 K (86 °F) using a pressure type impact tester [350]. The striker was made from 1/8-in sheet point. It was impacted on a 1/8-in-thick base or anvil plate at energy levels from 80 to 96 J (59.4 to 71 ft-lb). For most tests the striker and anvil plate were made from the same metal. A 150-g charge of ClF_5 was used for each test. This was sufficient liquid to cover the base plate to a depth of about 9.5 mm (3/8 in). No signs of ignition were seen for duplicate runs of the four metals in ClF_5 , where the striker and anvil plate were the same metal. There was no sign of ignition of the fresh metal surface that was exposed to the liquid ClF_5 impact. In all other respects, the metals that were impacted in ClF_5 or air were unaffected by the impact exposure. Ignition could not be initiated by impacting Al 2014-T6, magnesium AZ31B, Nickel 200, or CRES-347 in liquid ClF_5 at 303 K (30 °C). Tetrafluoroethylene (TFE) similarly impacted by CRES-410 was completely consumed in a rapid, highly exothermic reaction. The same apparatus and same metals were used for impact tests in liquid fluorine and dinitrogen tetroxide. Immersion in liquid ClF_5 at up to 303 K (30 °C) resulted in moderate weight gains for TFE and Kel-F plastics, complete and rapid reaction of columbium and molybdenum to salts, degradation of blocks of carbon and graphite to powders, and no change in titanium. Corrosion rates of nine other structural metals in liquid ClF_5 at 303 and 339 K (30 and 66 °C) were low (0.2 mil/year) but increased at 339 K (66 °C) for CRES-410 and yellow brass (0.7 mil/year).

Duplicate sets of 34 different materials of construction, exposed to the liquid and vapor phases of ClF_5 for a period of 19 months, exhibited corrosion rates similar to those demonstrated previously in 30-day materials compatibility studies under both ambient-temperature and 344-K (160 °F) conditions [351]. The 34 materials included 10 aluminum alloys, 4 stainless steels, Rene 41, Inconel-X, Hastelloy-C, nickel, Kel-F 81, FEP Teflon, TFE Teflon, PH15-7 Mo, tool steel AM-350, AM-355, 7 Monel alloys, and hard copper. Each container bomb assembly was constructed from a 10-in-long, 1-in-diameter stainless-steel tubing with a stainless-steel bellows-type valve at the top and a threaded plug in the bottom. The tube was lined with Kel-F sheet to prevent galvanic corrosion between the samples and the wall of the bomb. All aluminum alloys tested suffered weight losses in both the liquid-exposed and vapor-exposed specimens. The magnitude of the weight losses, which was similar for each alloy tested, was well within the corrosion resistance rating level (<2.0 mil/year) established as “excellent.” The 300-series stainless steels showed very small weight gains in the liquid-exposed samples and some conflicting results for the vapor-exposed samples. Of the non-austenitic stainless steels tested, the PH 15-7 Mo and AM 350 samples showed slight weight gains. Long-term exposure of the nickel and nickel base alloys to liquid ClF_5 resulted in small weight gains. The copper and Monel alloys, subjected to long-term exposure to ClF_5 , experienced weight gains of relatively slight to moderate

magnitudes. Although all of the Monel surfaces were discolored and dull, evidence for the attack on the two cast Monel alloys, 505 and 507, was demonstrated in the form of surface pitting in the area of the stamped identification markings. Long-term testing of the non-metallic fluorinated ethylene propylene (FEP) Teflon, TFE Teflon, and Kel-F 81, resulted in the expected large weight gains experienced in previous testing. All of the specimens absorbed small amounts of ClF_5 with magnitudes between materials running in the order of Kel – F81 > FEP Teflon > TFE Teflon. In addition to these tests, a selected group of samples was studied in a preliminary 30-day compatibility test with moisture- and air-contaminated ClF_5 at a controlled temperature of $303 \pm 1 \text{ K}$ ($86 \pm 2^\circ \text{F}$). The effects of this closed-system exposure, evaluated on the basis of visual inspection and weight gain/loss analysis, indicated that all the materials were compatible under the test conditions. The propellant storage test bombs were 6.5 in long, 1.5 in in ID, and had a 1/8-in wall thickness. The four bombs and their top flanges were machined from 321 stainless steel, 6061 aluminum, Monel 400 (cold), and oxygen-free copper stock respectively. Each bomb contained 300 g (167 cm^3) of high-purity ClF_5 . Periodic analyses of ClF_5 samples stored at ambient temperature in 321 stainless steel, 6061 aluminum, Monel 400 and oxygen-free copper containers (initial ullage of 20 to 30%) at ambient temperature for a period of 13 months indicated an absence of propellant decomposition and/or reaction.

The results of the 30-day tests were supplemented by the results of 580-day immersion tests with the same materials [352]. The alloys most resistant to attack by ClF_5 under all conditions were Hastelloy-C, nickel 210, René 41, and Inconel X-750. Metallurgy of sectioned and polished specimens when examined under the optical microscope revealed that several of the Monel alloys (Monel 400, R-405, 500, 501, and 507) suffered severe localized attack of second phases of inclusions (stringers). The localized corrosion was severe enough to exclude the use of these alloys from long-term contact with ClF_5 . In most cases, corrosion of alloys began with the formation of a passivation layer, which resulted in weight gain, but when the passivation layer flaked off, the sample would end up with a weight loss. Raising the temperature from ambient to 344 K (160°F) considerably increased the rate of corrosion. The weight change after 30 days at 344 K (160°F) was comparable with the weight change after 580 days at ambient. There was no noticeable attack on Teflon FEP, Teflon TEF, or Kel-F81, but these materials gained a lot of weight.

Eleven metallic materials of construction were included in a program to evaluate the compatibility of liquid and gaseous fluorine and chlorine pentafluoride with metals: 301 (cryoformed), 304L, 321, and 347 stainless steel; A-286 super alloy steel; Al-2219, Al-6061; oxygen-free copper; Monel K-500; Inconel 718; and Nickel 200 [249, 353]. Six different tests were performed to evaluate compatibility of metals with stagnant or flowing gaseous and liquid ClF_5 in comparison with fluorine: (1) maximum velocity, (2) adiabatic compression (U-tube), (3) liquid impact, (4) flexing/film degradation, (5) vibration/film degradation, (6) liquid phase shock wave.

(1) In the maximum allowable flow velocity, sections of heated tubing were tested with gaseous ClF_5 in the stagnant, subsonic, and sonic flow condition. Thermocouples attached to the outside of the tubing would quickly detect incipient ignition and consumption of the tubing wall from the inside until a burn-through occurred. The data showed that velocity had a relatively small influence on the potential failure threshold temperature of any of the metals studied in either F_2 or ClF_5 . Generally, copper, the stainless steels, and Inconel 718 had slightly lower threshold temperatures in the presence of ClF_5 than in F_2 under comparable flow conditions. The threshold temperatures of Monel K-500 and Nickel 200 were lower in the presence of F_2 than in ClF_5 .

(2) Maximum allowable temperature, pressure, and rate of adiabatic compression of propellant vapors tests were conducted in an adiabatic compression test apparatus with 2 to 3 mL of liquid oxidizer condensed in the U-tube. There was only slight erosion but no ignition. U-shaped tubing made from 12 different metals was filled with gaseous ClF_5 and compressed suddenly to 20.7 MPa (3000 psig). Only 3 positive (ignition) results were observed in the 60 tests and these occurred on 301 Cryo and 304-L stainless steels at the maximum pressurization capabilities of the test apparatus (3000 psig driving pressure) and with the ClF_5 vapor at an initial temperature of 373 K (212°F) or higher, whereas many more ignitions happened with gaseous fluorine. Once ignited, the tubes were completely consumed.

(3) The objective of the liquid maximum allowable velocity of impact tests was to determine the maximum temperatures to which the selected metals may be heated without detrimental effects occurring when impacted by liquid streams of fluorine or ClF_5 . The test simulates a situation that may occur during restarts during a heat-soak condition. The temperature of the metal specimens was measured by means of thermocouples attached to the back of the metal strip, which was 0.010 in thick. The metal specimens were placed within 3/16 in of the discharge orifice of the liquid propellant feed system. Two different impact velocities were tested at which the liquid slug would impact the metal specimen at 120 ft/s or 220 ft/s. The threshold temperatures for ignition for a given metal were all very close together, independent of impact velocity and the type of liquid oxidizer (LF_2 or LCIF_5). The results could be arranged in a sequence from the most sensitive metal, Al6061T6, igniting at 755 K (900°F), to the most resistant metal, nickel 200, igniting only above 1422 K (2100°F).

(4) The degradation of the passive film as a result of cyclic loading in liquid ClF_5 tests simulated conditions that are encountered by flexing bellows. Metal specimens were flexed by a reciprocating shaft 0.5 in in either direction at a rate of about 5 flexures per second. The fixture was actuated for 100000 cycles, then vented and dried. None of the samples ignited. The weight gain was 3–4 times higher for flexed specimens than for those in a static test in the same test fixture. The flexing of metal specimens in liquid ClF_5 did not significantly disrupt the passivation film.

(5) The objective of the sonic and ultrasonic vibration film degradation tests was to determine whether the “passivating film” on the selected metals undergoes appreciable degradation when subjected to vibration. The test simulated a situation such as

in pumping, in which cavitation occurs. Samples were immersed in liquid ClF_5 in an ultrasonic cleaning bath which was driven with 400 watts at a frequency of 62.5 kHz. 301 cryoformed stainless steel, Al-6061-T6 aluminum, and Ni-200 were unaffected by the vibration. CRES 347 and A-286 stainless steels and copper suffered slight weight losses in the vibration test.

(6) The effect of a shock wave test simulates the “water hammer effect” in the metallic materials produced during sudden valve closure. Nickel 200 was found to be suitable for use at temperatures up to 1228 K (1750 °F) in gaseous fluorine or chlorine pentafluoride. Inconel 718, under comparable testing, was suitable to 1116 K (1550 °F), whereas Monel K-500 could withstand 1089 K (1500 °F) except when subjected to adiabatic compression. The austenitic stainless steels were suitable at temperatures up to 866 K (1100 °F) except when subjected to adiabatic compression in chlorine pentafluoride. Copper and the aluminum alloys were resistant to attack at temperatures up to only 700 K (800 °F).

A modified Army Ballistic Missile Agency (ABMA) open-cup impact tester was used to measure the impact sensitivity of Al2014-T6 and Ti-6A-4V in liquid ClF_5 at a temperature between 173 K (−100 °C) and its boiling point [354]. The first six drop tests were conducted with the Al2014-T6 alloy at 95 J (70 ft-lb) and a temperature between 173 and 223 K (−100 and −50 °C). Two out of five tests gave faint flashes. A test procedure for bracketing the 50% probability of initiating a reaction was attempted, but only 1 positive reaction occurred at 93 J (69 ft-lb) out of 16 tests. Modified ABMA open-cup impact tests on annealed Ti-6A-4V (extra low interstitials; ELI) were conducted in liquid ClF_5 at boiling point. There were 15 reactions out of 29 tests. The impact energy required for a 50% probability of initiating a reaction in liquid ClF_5 was calculated to be 57.6 J (42.5 ft-lb). See also [208].

2.3.5.2 Compatibility of Chlorine Pentafluoride with Non-metallic Materials

The number and types of non-metallic materials that are compatible with ClF_5 is quite limited. Experimental efforts have shown that Kel-F and Teflon plastics and various fluorocarbon oils are compatible but only under limited conditions (i.e., static application at ambient temperature).

2.3.5.3 Long-Term Tank Storage Tests

Storable Prepackaged Propellant (SPP) systems of a liquid rocket propellant feed system were designed, fabricated, tested, and delivered by General Dynamics Convair for subsequent use in a storability investigation by the Air Force Rocket Propulsion Laboratory (AFRPL) [355]. The propellant tanks were fabricated of Al-2219 and had a volume of approximately 57 L (15 gallons). Each of the 23 delivered systems consisted of a 57-L propellant tank, which contained either a Surface Tension Force Orientation device or a Rolling Diaphragm positive expulsion device, along with one of three different pressurization subsystems, including a Liquid Propellant (hydrazine) Gas Generator, a Solid Propellant LFT-3 (ammonium nitrate composite) Gas Generator (SPGG),

or a Stored Gas Device. Within the gas storage bottle, 90% nitrogen/10% helium gas was contained at 20.79 MPa (3015 psia) by an explosive valve. Each tank was welded closed such that the propellant was contained within an all-metal, welded tank. Metal rupture discs, welded in the tank inlet and outlet, would rupture for propellant discharge when pressurized by the pressurization subsystem. The systems were delivered to AFRPL, hermetically sealed, and loaded with their respective propellants: Mixed Hydrazine Fuel (MHF-5), dinitrogen tetroxide (N_2O_4), or chlorine pentafluoride (ClF_5). In addition, four tanks were delivered empty to AFRPL. One sample of each of the storage subsystems was test fired shortly after being loaded with propellants and the pressure history and propellant flow rate were recorded. This served as a baseline for later comparison when the stored units were to be tested using the same procedure.

An incident happened while one SPP was being packaged for delivery to AFRPL. The system consisted of a rolling diaphragm tank loaded with 69.8 kg (154 lb) of ClF_5 and an SPGG pressurization subsystem. The ClF_5 had been loaded into the tank 20 days previously and the tank had always been maintained in a vertical position. When the tank was laid in a horizontal position to package for shipment, within 10 s after obtaining a horizontal attitude, a reactant noise came from inside the tank. Ninety minutes later the tank ruptured. Post-rupture examination showed that the weld between the liquid bulkhead and the tank cylinder had parted owing to high internal tank pressure. The ClF_5 had leaked through the rolling diaphragm or one of its weld joints and had combined with the silicon rubber to ignite and evolve gas.

The USAF Air Force Research Laboratory at Edwards AFB, CA, conducted tank storage tests with a large number of oxidizer and fuel tanks and published a series of interim progress reports over a period of two decades. The propellants under test were N_2O_4 , ClF_3 , ClF_5 , N_2H_4 , and MHF-5. Tankage materials under test were various alloys of aluminum, steel, and titanium. Tankage was joined by automatic and manual TIG welding, EB welding, and solid-state bonding techniques. There are many areas to consider when selecting tank storage test procedures in providing data to supplement coupon compatibility testing. Storage conditions must be selected that are representative of system operational conditions. Such factors as ambient humidity and temperature play an important role. A detailed propellant chemical analysis before and after testing is required to evaluate the effects of storage on the purity of the propellant. The program was structured as several parallel phases. Phase I used 3×6 -in bomblets from Al-2014-T6 for quick reference tests, one-quart (0.94-L) bomblets made by Alcoa from Al-2014-T6, Al-6061-T6, Al-7007-T6, Al-2219-T81, Al-5456-T6, Al-3003-T6, and Al-X2021-T-6, and cylinders made by Arde from cryoformed CRES-301. Phase II used 57-L (15-gallon) tanks made of Al-2219-T81 and AM350 steel for storability evaluation with N_2O_4 and ClF_5 . Phase III used 57-L (15-gallon) tanks from several aluminum, steel, and titanium alloys. Phase IV used existing tanks from Bullpup and Agena programs. Phase V used prepackaged feed systems built by General Dynamics/Convair, including electron-beam-welded Al-2219-T81 tankage loaded with N_2O_4 , ClF_5 , and MHF-5.

At the date of the first report, a significant number of liquid propellant tanks, fabricated by typical production methods of forming and welding and subjected to the same degree of inspection and quality control documentation as production tankage, had been evaluated in storage testing for nearly 2 years. A number of leaks were encountered in all three types of tankage metals, aluminum, steel, and titanium. In general, the failures were attributed more to quality discrepancies during fabrication and welding than to a lack of compatibility of the metals themselves [356].

Tank storage tests under extreme conditions of relative humidity and temperature (constant 303 K = 85 °F and 85% relative humidity for oxidizer systems and cycling between 294 and 339 K (70 and 150 °F) for fuel systems) in progress for 3–4 years indicated that leakage of propellant can occur as a result of improper weld joint design, inadequate quality control in fabrication, and insufficient acceptance leakage testing. During this period the cause of failure of a total of 12 tanks was analyzed [357]. Twelve Phase II integrated systems were loaded with ClF₅ and approximately 2 weeks later the environment in the oxidizer storage facility was maintained at 303 K (85 °F) and 85% relative humidity. One day, a month later, the storage facility was inspected and no systems were found to be leaking. Two days later, the facility was again inspected and a very large concentration of ClF₅ vapors was found. It was determined that at least two tanks were leaking ClF₅, (one a cryogenically stretch-formed AISI 301 stainless steel container, and one an integrated system with an AM350 steel tank). Numerous other tanks and systems were detanked because of corrosion damage to their external surfaces. The original leak was located in an aluminum tubing weld of a system containing ClF₅. The large concentration of HF (the product of ClF₅ hydrolysis) vapors resulting from the leaks also damaged the building's air conditioning system, which had to be rebuilt.

Later reports contained detailed metallurgical examination of failed tank shells and connecting tubing [358–360]. Stress corrosion cracking susceptibility of the tank material in combination with the propellant and trace quantities of foreign compounds/elements in the propellant can aggravate the situation.

Two chlorine pentafluoride samples that had been off-loaded from 5-year storage tests at AFRL and analyzed at Rocketdyne by GC and IR and showed full compliance with requirements of MIL-P-27413 with regard to ClF₅, ClF₃, HF, and other impurities [361].

Tanks that had held chlorine pentafluoride and had been stored in a controlled storage environment at 303 K (85 °F) and 85% relative humidity for several months were emptied, cleaned, and dissected for metallurgical analysis [362]. The corrosion effects of the stored propellants on the internal metal surfaces were negligible, with no serious degradation of strength or structural integrity occurring. Corrosion was primarily caused by pitting, gas, and liquid phase interactions occurring during storage, manufacturing defects, and at the manifold tubing welds.

2.3.6 Components for Chlorine Pentafluoride Service

2.3.6.1 Valves for Chlorine Pentafluoride Service

A failure analysis of a thrust chamber valve from an attitude control system that had been returned from ClF₅ service examined various failure modes (overstressing of the closures, corrosion, abrasive wear, and impact-initiated reactions) and conducted additional materials compatibility tests to evaluate candidate materials [363]. Corrosion caused by residual water in the valve was one of the most likely failure modes. The modes studied included overstressing of the closures by closing loads, adhesive wear of the closure surfaces/corrosion of the closures by ClF₅, and HF/abrasive wear, corrosive wear, and impact-initiated surface reactions. Equations that relate valve wear to operating and material parameters were developed during the analysis. For all of the normal modes of possible failure investigated, the valve was considered to be adequately designed to withstand any expected level of load or attack as long as it was kept dry.

Tests conducted to select seat and poppet materials and/or sealing concepts for use in ClF₅ attitude control system valves evaluated nickel-, iron-, tungsten-, and zirconium-based materials in the flat-on-flat sealing concept, as well as a sapphire/copper lip-seal concept [364]. Two varieties of tungsten carbide in the flat-on-flat configuration (Kennametal 96 and Kennametal 801) were the only materials that met the leakage requirement of <30 cm³ helium/h after 100000 actuations in ClF₅.

A bipropellant solenoid valve showed extensive finish deterioration of both the poppet and the seat mating surfaces after being operated in ClF₅ [365]. Surface roughness measurements on poppets exposed to ClF₅ revealed that the surface finish deterioration was far more severe in sealing and impact areas than on non-sealing surfaces. A method was developed for determining the mechanism of sealing surface deterioration in halogen fluoride oxidizers.

2.3.6.2 Cleaning of Components for Chlorine Pentafluoride Service

A detergent cleaning technique developed by Aerojet Propulsion Division that eliminates the use of chlorofluorocarbon (CFC) fluids in the cleaning of rocket engine test systems and components (valves, filters, check valves, turbine flow meters, pressure transducers, and tubing) was successfully demonstrated during the construction and operation of a rocket engine test facility that used chlorine pentafluoride and hydrazine propellants during the testing of engine components at thrust levels up to 4448 N (1000 lb_f) [366]. The test stand components had to be cleaned to a particulate level 100 (no particles greater than 100 μm), a non-volatile residue value less than 43.1 mg/m² and a hydrocarbon content less than 10.8 mg/m² of significant surface area. The flow paths were less than 1.27 cm (0.5 in.) in diameter. The facility has been used to successfully conduct over 5500 thruster static hot firings, propellant tank sub-system tests, and a full system hot fire demonstration consisting of three engines, three propellant tanks, and associated propellant delivery and pressurization subsystems.

2.3.7 Toxicity of Chlorine Pentafluoride

Groups of rats, mice, dogs, and monkeys were exposed to various measured concentrations of ClF_5 to determine the 15-, 30-, and 60-min inhalation and whole-body exposure LC50 for each species [367, 368]. All animals were observed for visible symptoms and mortality both during exposure and for 14 days post-exposure. The LC50 values (in ppm) for rats were 257, 194, and 122; for mice 144, 105, and 57; for dogs 298, 156, and 122; and for monkeys 249, 218, and 173, for 15-, 30-, and 60-min exposures respectively. The respiratory tract was the primary target for ClF_5 damage in all four species, and mortality due to ClF_5 exposure was related to its adverse respiratory effects. The LC50 information from this study was compared with LC50s obtained for other fluorinated oxidizers and HF. Chlorine pentafluoride was less toxic than OF_2 , but was more toxic than either ClF_3 or HF. It was also found that mice were the least resistant to ClF_5 exposure. These experiments showed that ClF_5 is extremely toxic to each of the four species tested. See also [235, 369].

2.3.8 Environmental Impact of Chlorine Pentafluoride

Like many fluorocarbon compounds, ClF_5 may have deleterious effects on the ozone layer owing to its release of HF and HCl once it hydrolyzes. However, it is unlikely that any releases of ClF_5 would diffuse all the way to the ozone layer unreacted. Before they got there, they would hydrolyze with atmospheric moisture and be photolyzed by UV in the upper atmosphere.

2.3.8.1 Atmospheric Dispersion of Accidental Chlorine Pentafluoride Releases

An assessment of the launch safety, human toxicity, and environmental impact associated with ClF_5 usage and examination of the hazards resulting from a prelaunch propellant handling and loading accident and from a launch vehicle explosion at the launch site or in-flight was based on known toxicity values for ClF_5 and atmospheric dispersion models [370]. The operational use of ClF_5 may require a more detailed review of personnel safety, industrial hygiene, and handling procedures, especially for transport on public highways. The reactivity of ClF_5 and incompatibility with materials makes it more hazardous than N_2O_4 . For this case of liquid ClF_5 spills, three accident scenarios were considered:

- (1) prelaunch accidents such as during propellant handling and loading leading to an uncombusted cold propellant spill,
- (2) a launch site explosion creating a plume of propellant combustion products settling over the immediate ground area,
- (3) an in-flight explosion dispersing propellant combustion products into the troposphere and stratosphere depending on altitude.

The impact of these accidents is examined in terms of their environmental effects on: (1) human toxicity, (2) animal and plant toxicity, including land and sea life,

(3) atmospheric disturbance in terms of pollution (troposphere) and ozone depletion (stratosphere). Accident scenarios were modeled for cases of ground-based cold and combusted propellant releases and post-launch explosions in the troposphere and stratosphere. Each assessment was supported by a simple worst case model and calculation. More realistic calculations for ClF_5 release and dispersion were then presented based on the Air Force Toxic Chemical Dispersion Model (AFTOX) dispersion model for toxic chemical releases. Ground-based accidents were modeled for a range of weather conditions reported for the most probable sites of accidents at Vandenberg AFB. The effect of ClF_5 on microorganisms, fish, and plants has already been reported [244, 245]. As a group, interhalogens, including ClF_5 , have damaging effects on plants for 10- to 30-ppm exposures of less than 1 h, and are lethal to fish and microorganisms at concentrations of 10–25 mg(F)/L. It was assumed that the ClF_5 is converted mostly to HF within the timescale for expression of toxic effects. A recommended ClF_5 TLV of 2.5 mg(F)/m³ (0.4 ppm) TWA has been adopted by the Occupational Safety and Health Administration (OSHA), the American Conference of Governmental Industrial Hygienists (ACGIH), and the National Institute of Occupational Safety and Health (NIOSH). In the atmosphere ClF_5 most likely hydrolyzes quickly; hence, the toxic and environmental impact should take into consideration the importance of HF. The ACGIH TLV for HF is 2 mg/m³ (3 ppm). A simple calculation was presented for an instantaneous ground-based release that disperses homogeneously and uniformly into a hemisphere centered at the spill site. This model assumes no wind, eddy currents, or vertical convection forces to disperse the plume. No dynamics were included: it was calculated in how large a volume the release must expand to in order for the concentration to fall below some threshold exposure level. The toxic chemical release code AFTOX is used by the Air Force for disaster response and emergency preparedness. AFTOX assumes that gaseous chemicals are carried at wind velocities and that the moving chemical volume spreads out as a Gaussian distribution. The rate of spread or dispersion depends on an atmospheric stability factor determined from wind speed, temperature, sun elevation (computed from location, date, and time), cloud cover and type, and roughness of ground terrain. The model does not allow for changes in wind speed and direction, nor does it treat vertical dispersion by convection from actual thermal gradient information. Vertical dispersion is accounted for solely by the atmospheric stability factor. The AFTOX results show concentration/time profiles along the center axis of the wind vector or in a 2-D plot show equi-concentration lines of the plume shape at different times as a function of wind speed and other parameters. For a release of 2000 kg ClF_5 and a wind speed of 0.5 m/s, the maximum concentration drops below the TLV only after the plume has traveled more than 1 km. The results were compared with two NASA studies that evaluated the short-term acute effects from fluorine propellant accidents [371, 372]. Damaging effects can occur to plants for 10–30 ppm (200 mg/m³) exposures of less than 1 h.

2.3.9 Detonability of Chlorine Pentafluoride

Detonation sensitivity tests proved that ClF_5 is insensitive to initiation and will not propagate a detonation. Impact sensitivity tests with a modified JANAF drop-weight tester in dry nitrogen and dry air at liquid temperatures up to 255 K (0 °F) showed no evidence of detonation up to 100 in-lb, the limit of the tester. A modified cap-in-pipe test in 1/2-in CRES tubing at 255 K (0 °F) resulted in no evidence for propagation of a detonation initiated by a 50-g Compound C charge and blasting cap. Additional adiabatic compression tests with the U-tube apparatus demonstrated the insensitive nature of ClF_5 to adiabatic compression stimulus over a variety of selected “worst conditions” (both air and water contaminated). The insensitive nature of ClF_5 was also confirmed by a standard Trauzl block test [248].

2.4 Chlorine Heptafluoride???

The highest fluorinated form of chlorine so far, ClF_5 , caused quite a stir in the world of chemistry and rocketry when it was first discovered in the 1960s. Now, computational chemists are pushing the limit even higher, all the way to the heretofore unknown chlorine heptafluoride ClF_7 . They argue “*If iodine can amass seven fluorines around it, why not chlorine?*” The fact that the heptafluoride of chlorine does not exist can be explained by steric arguments (there just is not enough space surrounding the chlorine atom).

Several attempts to prepare chlorine heptafluoride, ClF_7 , have been unsuccessful [373]. As part of the same effort, the group also attempted the synthesis of chlorine oxygen pentafluoride, OClF_5 , but without success. Earlier efforts by the same group were aimed at the synthesis of ClF_6SbF_6 as an intermediate to higher halogen oxidation state fluorides [374]. Preliminary IR spectroscopic data on the products of reactions in Monel reactors had been interpreted as showing the probable synthesis of ClF_6^+ . However, subsequent reactions in aluminum reactors established that the compound was not formed unless either copper or nickel was present. The reaction was not catalyzed by a small amount of nickel. Thus, although the possibility that the material was ClF_6SbF_6 could not be completely eliminated, it seemed likely that the product was a complex metal salt formed as a contaminant.

Numerous *ab initio* MO and DFT calculations were made to predict the stability and C—F bond strengths in ClF_7 and its ions in comparison with ClF_5 and ClF_3 stability. Predictions were made for the missing experimental thermochemical data of unknown chlorine fluorides and their ions [375].

Ab initio electronic-structure calculations were performed for the hypervalent chlorine fluorides, ClF_3 , ClF_5 , and ClF_7 , in order to determine their predicted thermodynamic stabilities with respect to dissociation to ClF and F_2 [376]. The calculations included electron correlations and extended basis sets and produced estimated energies of 100.4 and 176 kJ/mol (24 and 42 kcal/mol) for the predicted

stability of ClF_3 and ClF_5 respectively. The more symmetrical molecule was predicted to be more stable than the T-shaped molecule. Calculations on the D_{5h} symmetry structure of ClF_7 indicated that this system is unstable with an energy barrier of only 67 kJ/mol (16 kcal/mol). See also [377].

Gaussian-3 (G3) and Gaussian-3X (G3X) models of theory have been used to calculate the thermochemical data for chlorine fluorides ClF_n , $n = 1-7$, as well as for their singly charged cations and anions and heats of formation (ΔH_f), bond dissociation energies (DEs) of all of the species, ionization energies (IEs), and electron affinities (EAs) of the neutrals, have been tabulated [378]. By comparing well-established experimental data of ClF and ClF_3 with the G3 and G3X results, it was found that the G3X method actually yielded more accurate ΔH_f values. In addition, the G3 values on the IEs and EAs for ClF and ClF_3 were similar to the corresponding G3X results. Predictions were made for the missing experimental thermochemical data of unknown chlorine fluorides and their ions. An alternating pattern of the ΔH_f , DE, IE, and EA values of the ClF_n and their ions with system size n was discovered.

The bonding energies in the ClF_n ($n = 1-7$) series were calculated to further examine the explanatory usefulness of the recoupled-pair bonding model [379]. Optimized structures and energies of the ground and low-lying excited states of the ClF_n molecules were determined by employing high-level *ab initio* calculations with correlation-consistent basis sets. The bond energies for F addition to form ClF_2 , ClF_4 , and ClF_6 were found to be much lower than those leading to ClF , ClF_3 , and ClF_5 . The same type of alternating behavior had been observed in the SF_n series. The differences between ClF_n and SF_n reflect the fact that the $3s^2$ and $3p^2$ electron pairs are more strongly bound in Cl than in S. This behavior and other trends observed in the ClF_n species demonstrated the improved predictive ability of the recoupled-pair bonding model theory over other models for describing hypervalent bonding.

Chlorine heptafluoride, ClF_7 , may not yet exist, but that has not prevented the Chemical Abstract Service from already assigning registry numbers to it: CAS RN [478167-13-4] and [32825-94-8]. So, keep looking.

3 Bromine Fluorides

There are three known bromine fluorides with different states of oxidation (Br^{+1} , Br^{+3} , and Br^{+5}), but only the latter two are thermally stable. Bromine monofluoride decomposes at temperatures as low as near 273 K (0 °C). It would be nice to have a stable bromine heptafluoride, similar to iodine heptafluoride, but that is not the case. As the bromine atom is bigger than the chlorine atom, it might be possible to attach more oxygens in addition to the fluorines to create bromine oxide fluorides, but those compounds have not found any application. Bromine fluorides could be used as fluorinating agents in the synthesis of other high-energy oxidizers.

As rocket propellants, bromine fluorides have no advantage over chlorine fluorides. The more than two times heavier atomic mass of the central atom, 79.9 for bromine as opposed to 35.45 for chlorine, results in a higher average molecular mass of the combustion products and a lower exhaust velocity. Bromide minerals are not as readily available from salt mines as chloride minerals.

3.1 Bromine Trifluoride

Bromine trifluoride, BrF_3 , CAS RN [7787-71-5], is a clear, greenish colored liquid. It is not suitable as a rocket propellant because it has an inconveniently high freezing point at 281.9 K (8.8°C). The inconveniently high freezing point can be lowered by mixing with bromine pentafluoride. Bromine trifluoride will not be used as a rocket propellant, but it can be used as an intermediate in the synthesis of other fluoride compounds.

3.1.1 Preparation of Bromine Trifluoride

Bromine trifluoride can be prepared from the elements in an exothermic reaction at room temperature, but the product also contains some of the other bromine fluorides [380]. Moissan, the discoverer of fluorine, already found that fluorine gas combined violently with bromine vapor in the cold with a bright flame. When fluorine was passed through liquid bromine, combination was also immediate but without flame. Bromine trifluoride was also formed when alkaline metal bromides were reacted with fluorine:

One of the manufacturers of bromine fluorides, Allied Chemical, once (in the early 1960s) published product information bulletins that contained a good summary of physical properties of BrF_3 and BrF_5 , but those brochures are no longer available from this source. Most of the data in the following two tables were taken from that historical source. There is currently no domestic source for bromine trifluoride in the USA.

3.1.2 Physical Properties of Bromine Trifluoride

The physical properties of bromine trifluoride are summarized in Table 36. A complete source of physical properties of BrF_3 is the NIST Chemistry WebBook [381].

Table 36: Physical properties of bromine trifluoride.

Property	SI Units	MKS Units	Source	References
Molecular mass	136.899		NIST Chem WebBook	[38]
Freezing point	281.9 K	+8.8 °C	Allied Chemical	
	281.9 K	+8.8 °C	Stein, Vogel, and Ludewig 1954	[382]
Boiling point	400 K	127.6 °C	Allied Chemical	
	398.95 K	125.8 °C	Stein, Vogel, and Ludewig 1954	[382]
	398.85 K	125.7 °C	Air Products & Chemicals MSDS	
Critical temperature	601 K	328 °C	Air Products & Chemicals MSDS	

3.1.2.1 Density of Bromine Trifluoride

The density of liquid BrF_3 as a function of temperature can be calculated from the following linear equation:

$$\rho = 3.623 - 0.00277T$$

where ρ is the density in g/cm^3 and T is the temperature in kelvin. The density of bromine trifluoride at 50 °C was found to be $2.7351 \pm 0.0005 \text{ g/mL}$, and that of bromine pentafluoride at 0 °C was found to be $2.5475 \pm 0.0005 \text{ g/mL}$. The approximate temperature coefficients of density were $-0.00272 \text{ g mL}^{-1} \text{ }^\circ\text{C}^{-1}$ from 23 to 50 °C for the trifluoride and $-0.00348 \text{ g mL}^{-1} \text{ }^\circ\text{C}^{-1}$ from 0 to 25 °C for the pentafluoride [382]. The density of $\text{BrF}_3/\text{BrF}_5$ mixtures at 298 K (25 °C) can be calculated from the equation

$$\rho = 2.8030 - 0.3884M_2 + 0.0641M_2^2 - 0.0183M_2^3$$

where ρ is the density in g/cm^3 and M_2 is the mol fraction of BrF_5 .

3.1.2.2 Vapor Pressure of Bromine Trifluoride

The vapor pressure of BrF_3 can be represented by the following logarithmic equation:

$$\log p_v = 7.74853 - 1685.8/(t + 220.57)$$

where p_v is the vapor pressure in mm Hg and t is the temperature in °C. A different form of the vapor pressure equation is

$$\log p_v = 8.41954 - 2220.2/T$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin.

Early investigators of BrF_3 , Ruff and Braidia (1933) [383] had measured the vapor pressure only over a limited pressure range, 4 to 136 mm Hg. Thirty years later, an investigation extended the vapor pressure data to 2.5 atm on material of high purity. The vapor pressure and heat of vaporization of bromine trifluoride was measured over the

range 312 to 428 (39 to 155 °C) and the following equation was derived by methods of least squares to represent the experimental data [384, 385]:

$$\log_{10} p = 7.74853 - 1685.8/(t + 220.57)$$

where p is the vapor pressure in mm Hg and t is the temperature in °C. A different but very accurate vapor pressure equation for the temperature range from 336 to 453 K (63 to 180 °C) was derived by [386, 387]:

$$\log_{10} p_v = 7.65757 - 1627.5/(t + 215)$$

where p_v is the vapor pressure in mm Hg and t is the temperature in °C.

The vapor phase diagram of BrF₃/BrF₅ mixtures is illustrated in Figure 43. The activity coefficients for these mixtures were tabulated (not shown here).

Figure 43: Liquid-vapor diagram of the BrF₃/BrF₅ isobar system, data adjusted to 1 atm. (Reprinted and modified from [387], with permission from © 1958 American Chemical Society.)

3.1.2.3 Optical Properties of Bromine Trifluoride

As the refractive indexes of BrF₃ and BrF₅ are quite different, it should be possible to analyze BrF₃/BrF₅ mixtures as they often are formed during fluorination of bromine by refractive index measurements. At 298 K with the sodium D line, the refractive index of BrF₃ was 1.4536 and the refractive index of BrF₅ was 1.3529 [382]. The IR spectra of

bromine fluorides were studied in an IR cell whereas the bromine was reacting with elemental fluorine or bromine trifluoride [388]. The IR spectra of BrF_3 were compared with those of ClF_3 . The Raman and IR spectra of ClF_3 and BrF_3 gave strong support for a planar T-shaped molecule [83, 84, 87].

In the IR spectrum of matrix-isolated BrF_3 , all six fundamental vibrations expected for a T-shaped molecule of symmetry C_{2v} were observed [389]. Raman spectra of the liquid indicated strong association in the liquid phase through formation of fluorine bridges. A modified valence force field and some thermodynamic properties have been computed for BrF_3 . The differential enthalpy of formation of gaseous (ideal gas at 1 atm) BrF_3 is $(\Delta H_{298} - \Delta H_0) = 14.70 \text{ kJ/mol} = 3.513 \text{ kcal/mol}$.

3.1.2.4 Electric Properties of Bromine Trifluoride

Owing to the autodissociation

bromine trifluoride has a specific conductivity at 288 K (15 °C) of $8.1 \times 10^{-3} \Omega^{-1} \text{ cm}^{-1}$, which strangely enough decreases as the temperature increases from 288 to 333 K (15 to 60 °C) [121]. Among the four halogen fluorides ClF_3 , BrF_3 , BrF_5 , and IF_5 , BrF_3 has the highest electrical conductivity [390, 391].

Dielectric constants and dipole moments of BrF_3 and IF_5 were already shown in earlier tables in the ClF_3 Section 2.2.2 for comparison. A planar T-configuration for BrF_3 , similar to that now established for ClF_3 , accounted satisfactorily for the dipole moment of this molecule.

3.1.2.5 Thermodynamic Properties of Bromine Trifluoride

A complete source of thermochemical properties of BrF_3 is in the NIST Chemistry Web-Book [381]. Thermodynamic properties of BrF_3 are summarized in Table 37.

The heats of formation of bromine fluorides previously had been derived from spectroscopic and equilibrium data and estimated from bond energy considerations. The following is the first calorimetric measurement of the heat of reaction of $\text{F}_2 + \text{Br}$, which happens to be the same as the heat of formation. The heats of reaction of F_2 with Br were measured with an adiabatic calorimeter in the vicinity of 298 and 378 K (25 and 105 °C) [392]. When excess F_2 was used, BrF_3 and BrF_5 were formed in the 298 K (25 °C) region, and BrF_5 alone was formed in the 378 K (105 °C) region. The standard heats of formation (ΔH_f) of BrF_5 , BrF_3 , and BrF calculated from the measurements were -444.3 , -271.1 , and -74.1 kJ/mol (-106.2 , -64.8 , and -17.7 kcal/mol), respectively (reactants and products in the gaseous state at 298 K = 25 °C). The standard free energies of formation [ΔF_f] were -351.9 , -231.0 , and -75.3 kJ/mol (-84.1 , -55.2 , and -18.0 kcal/mol) respectively.

Table 37: Thermodynamic properties of bromine trifluoride.

Property	SI Units	Other units	Source	References
Enthalpy of formation, gas (ΔH) ₂₉₈ ^f	-255.6 ± 2.9 kJ/mol	-61.1 ± 0.7 kcal/mol	Stein 1962	[392]
Enthalpy of formation, gas (ΔH) ₂₉₈ ^f	-255.59 kJ/mol	-61.087 kcal/mol	NIST WebBook, Chase 1998	[38]
Heat of fusion, at triple point of 281.93 K	12.027 kJ/mol	$2.874.6 \pm 3$ kcal/mol	Oliver and Grisard 1952	[385]
Heat of evaporation (ΔH) _{evap} at the normal boiling point, 398.9 K (125.75 °C)	42.68 kJ/mol	10.2 kcal/mol		
Entropy, liquid BrF ₃ at 298.16 K	178.1 J K ⁻¹ mol ⁻¹	42.57 ± 0.10 cal °C ⁻¹ mol ⁻¹		
Entropy, ideal gas BrF ₃ at 298.16 K	299.4 J K ⁻¹ mol ⁻¹	71.57 cal °C ⁻¹ mol ⁻¹		

The heat of evaporation of BrF₃ was estimated from vapor pressure data by the following equation, which is based upon the Clausius–Clapeyron relation [384]:

$$\Delta H_{\text{vap}} = 7714[(t + 273.16)/(t + 220.57)]^2$$

where ΔH_{vap} is the heat of evaporation in cal/mol and t is the temperature in °C.

3.1.3 Chemical Properties of Bromine Trifluoride

In air, particularly in moist air, the liquid emits white acid fumes. Bromine trifluoride is not as strong an oxidizer as ClF₃ or F₂. Organic materials may not all inflame instantly when coming into contact with BrF₃ and some may require an external source of ignition if this is intended as a rocket propellant. Diethyl ether, benzene, and turpentine ignite instantly with bromine trifluoride.

Similar to chlorine and some iodine fluorides, bromine trifluoride forms fluorobromate(III) and fluorobromonium salts, which are potentially useful as solid propellant oxidizers and fluorinating agents [393–395].

3.1.4 Handling of Bromine Trifluoride

Bromine trifluoride can be handled in all materials of construction that are also acceptable for ClF₃. Similar to the passivation of metals with other reactive fluorides, metals eventually passivate in BrF₃ and be protected from further attack (as long as the film does not dissolve in BrF₃!). In the case of BrF₃, it is a better solvent than F₂

or ClF_3 and it forms many tetrafluorobromates with common metals, such as silver. AgBrF_4 is soluble in BrF_3 .

As far as handling precautions are concerned, BrF_3 is just as toxic as the other halogen fluorides and causes severe skin burns that heal only very slowly. The deep burns will often lead to subsequent complications such as skin edema and necrosis of the surrounding tissue. Additional information on safe handling of BrF_3 can be found in the Safety Data Sheets of former BrF_3 manufacturers, such as Air Products & Chemicals [396].

3.1.5 Toxicity of Bromine Trifluoride

The legal airborne permissible exposure limit (PEL) is 0.1 ppm averaged over an 8-h work shift (OSHA and ACGIH). The recommended airborne exposure limit is 0.1 ppm averaged over a 10-h work shift or 0.3 ppm not to be exceeded during any 15-min work period (NIOSH).

3.1.6 Applications of Bromine Trifluoride

Bromine trifluoride has few other industrial applications and is not particularly suitable as a rocket propellant. It has been tested as an ignition fluid for solid propellants, but does not offer any particular advantages over ClF_3 , other than the lower vapor pressure at room temperature. Chlorine trifluoride, bromine trifluoride, and bromine pentafluoride were evaluated as hypergolic ignition sources for double-base or composite propellants. Chlorine trifluoride was the best ignition fluid [397, 398].

Because BrF_3 is easier to keep as a liquid at room temperature than ClF_3 and has a similar reactivity with metals, it has also been used as a chemical cutting tool in cutting casings and stuck drill strings in oil and gas field drilling applications.

3.2 Bromine Pentafluoride

Bromine pentafluoride, BrF_5 , is a colorless liquid with a pungent, acrid odor, CAS RN [7789-30-2]. Bromine pentafluoride will most likely not be used as a rocket propellant, but it is useful as an intermediate in the synthesis of other fluorine compounds.

3.2.1 Preparation of Bromine Pentafluoride

Bromine pentafluoride can be prepared by reaction of bromine trifluoride with fluorine or by elemental synthesis from the elements themselves. For making bromine pentafluoride, Ruff and Menzel heated bromine trifluoride to 363–373 K (90–100 °C), mixed the bromine trifluoride vapors with fluorine, and then heated the mixture to 473 K (200 °C) in a platinum tube. By fractional condensation of the gaseous products, bromine pentafluoride was separated from the reaction mixture. After an ex-

plosion, however, the two-step process in platinum was abandoned in favor of direct combination of bromine and fluorine to bromine pentafluoride in a copper apparatus at 473 K (200 °C). Purification was accomplished by condensing the entire reaction mixture and then fractionally distilling it in quartz. Bromine pentafluoride also can be prepared by reaction of potassium bromide in an autoclave at high pressures and temperatures with an excess of fluorine [266].

3.2.2 Physical Properties of Bromine Pentafluoride

At room temperature, bromine pentafluoride is a liquid similar to bromine trifluoride. In spite of its higher molecular mass, bromine pentafluoride is more volatile than bromine trifluoride. Among the many non-metallic fluorides, the high density of bromine pentafluoride is remarkable. The physical properties of BrF₅ are summarized in Table 38.

Table 38: Physical properties of bromine pentafluoride.

Property	SI Units	MKS Units	References
Molecular mass	174.896016		[40]
Melting point	210.6 K	−62.5 °C	
	212.6 K	−60.5 ± 0.1 °C	[399]
	211.8 K	−61.3 °C	[382]
Boiling point	313.4 K	40.3 °C	
	313.9 K	40.76 ± 0.05 °C	[399]
	314.4 K	41.3	[382]
Critical temperature	~470 K	~197 °C	
Density at 298 K	2460 kg/m ³	2.4604 g/cm ³	[382]
Refractive index n_D^{25}		1.3529	[382]

The density of bromine pentafluoride as a function of temperature can be calculated from the following linear equation:

$$\rho = 3.496 - 0.00346 T$$

where ρ is the density in g/cm³ and T is the temperature in kelvin. The vapor pressure curve of BrF₅ is represented by the following logarithmic equation, based on old data by Ruff and Menzel:

$$\log p_v = 8.0716 - 1627.7/T$$

where p_v is the vapor pressure in mm Hg and T is the temperature in kelvin.

A slightly different equation was offered by Rogers and Speirs [399]: The vapor pressure as a function of temperature was found to be given by the expression

$$\log p = 7.9727 - 1598.2/T$$

with a probable error of ± 1 mm Hg over the range from 53 to 101 kPa (400 to 760 mm Hg), where p is the vapor pressure in mm Hg and T is the temperature in kelvin. A third equation for the range from 203.8 to 313.5 K was derived by Stull 1947 [400] from data by other investigators:

$$\log_{10} P = 4.79777 - [1411.692 / (T - 19.763)]$$

where P is the vapor pressure in bar and T is the temperature in kelvin. The molar entropy of vaporization calculated from these data is then 23.3 e.u., a reasonable value for a non-associated liquid composed of molecules with a dipole moment of 1.51 D.

Another different vapor pressure equation for BrF_5 for the temperature range from 298 to 419 K (25 to 146 °C) was derived by [387]:

$$\log_{10} p_v = 6.4545 + 0.001101t - 895 / (t + 206)$$

where p_v is the vapor pressure in mmHg and t is the temperature in °C.

The specific electrical conductivity of BrF_5 is much lower than that of BrF_3 . It is only 9.1×10^{-8} Ohm cm.

The molecular structure of BrF_5 was compared with that of BrF_3 and IF_5 [401]. Complete three-dimensional data were recorded at 153 K = -120 °C. The crystal system is orthorhombic, with $a = 6.422$ Å, $b = 7.245$ Å, $c = 7.846$ Å, $Z = 4$, and space group C_{2v} .

3.2.2.1 Thermodynamic Properties of Bromine Pentafluoride

Thermodynamic property data of bromine pentafluoride are summarized in Table 39.

Table 39: Thermodynamic properties of bromine pentafluoride.

Property	SI Units	MKS Units	References
Enthalpy of formation, gas $(\Delta H)^\circ_{298}$	-428.72 kJ/mol	-102.5 kcal/mol	[40]
	-429 $\pm$ 2 kJ/mol	-102.5 $\pm$ 0.5 kcal/mol	[392]
	-519 kJ/mol	-124.0 kcal/mol	[72]
Heat of fusion $(\Delta H)_{\text{melt}}$ (at 211 K = -62 °C)	7.28 kJ/mol	1.74 kcal/mol	
Heat of evaporation $(\Delta H)_{\text{vap}}$ (at 313 K = 40 °C)	30.1 kJ/mol	7.20 kcal/mol	
	30.6 kJ/mol	7.31 kcal/mol	[399]
Entropy of evaporation $(\Delta S)_{\text{vap}}$ (at 313 K = 40 °C)	97.5 J K ⁻¹ mol ⁻¹	23.3 e.u. =	[399]
		23.3 cal °C ⁻¹ mol ⁻¹	

3.2.3 Chemical Properties of Bromine Pentafluoride

Bromine pentafluoride reacts with essentially all known inorganic and organic compounds, with the exception of the other halogen fluorides in their highest state of fluorination. It ignites spontaneously with many other elements and metals. It ignites

spontaneously with all organic compounds with the exception of a few perfluorinated hydrocarbons. This remarkable reactivity makes it suitable as a hypergolic oxidizer.

3.2.3.1 Fluorobromate and Fluorobromonium Salts

Similar to chlorine and some iodine fluorides, bromine trifluoride and bromine pentafluoride form fluorobromate and fluorobromonium salts, which are potentially useful as solid propellant oxidizers or fluorinating agents.

The fluorobromonium salts $\text{BrF}_6^+ \text{AsF}_6^-$ and $\text{BrF}_6^+ \text{Sb}_2\text{F}_{11}^-$ can be synthesized from BrF_5 and the corresponding Lewis acids [402, 403]. In analogy with $\text{IF}_6^+ \text{AsF}_6^-$ crystals, the space group of $\text{BrF}_6^+ \text{AsF}_6^-$ crystals is $Pa\bar{3}$. See also [404].

$\text{BrF}_4^+ \text{AsF}_6^-$ has been prepared from BrF_5 and AsF_5 . It is marginally stable at 178 K (-95°C).

3.2.3.2 Analysis of Bromine Pentafluoride

Mass spectrometric analysis of BrF_5 showed that the strongest peak was $^{79}\text{BrF}_4$ [345]. The $^{79}\text{BrF}_5$ peak was only very weak, 1% of that of the strongest peak. SiF_4 and HBr were detected as contaminants.

3.2.4 Toxicity of Bromine Pentafluoride

The exposure limits for bromine pentafluoride are: 0.1 ppm (0.7 mg/m^3) OSHA TWA; 0.1 ppm ACGIH TWA; 0.1 ppm (0.7 mg/m^3) NIOSH [235].

4 Iodine Fluorides

There are four known iodine fluorides, corresponding to four different states of oxidation of the central iodine atom, I^+ , I^{+3} , I^{+5} , and I^{+7} . The physical properties of the upper two iodine fluorides were included in Tables 2–5 at the beginning of this section on halogen fluorides. At best, the latter two are potentially of interest as rocket propellants because they have a high fluorine content and they have a high density. However, iodine is not as readily available in bulk quantities as chlorine and the advantages of iodine fluorides do not outweigh their disadvantages, the main disadvantage being the high molecular mass of exhaust products and low specific impulse compared with that achieved with chlorine fluorides as the oxidizers. Iodine heptafluoride has such a high freezing point and narrow liquid range that it is not practical as a liquid rocket propellant. The main interest in iodine pentafluoride and iodine heptafluoride is in their molecular structure, to see by analogy of the electronic structure if heptafluorides can be synthesized for bromine and chlorine as well. Once the synthesis of heptafluorides was shown to be feasible for iodine, it was hoped that methods could be found to do the same trick for bromine or even chlorine. As rocket propellants, iodine fluorides have no advantage over chlorine fluorides. The more than three times heav-

ier atomic mass of the central atom, 126.9 for iodine as opposed to 35.45 for chlorine, results in a higher average molecular mass of the combustion products and a lower exhaust velocity. Iodine fluorides would not be used as rocket propellants, but they can be used in the synthesis of other fluorides.

4.1 Iodine Pentafluoride

Iodine pentafluoride, IF_5 , CAS RN [7783-66-6] is a colorless or yellow liquid, depending on the purity of the sample. Iodine pentafluoride will most likely not be used as a rocket propellant, but it is a useful intermediate in the synthesis of other fluorine compounds.

4.1.1 Preparation of Iodine Pentafluoride

The main preparation methods for iodine pentafluoride include: combustion reaction of solid iodine in fluorine gas, combustion reaction of liquid iodine in fluorine gas, or treating alkyl iodides with fluorine gas. The combustion reaction of iodine in fluorine gas is the most commonly used preparation method that has been industrialized [405]. Fluorine gas ignites iodine, burning it with a pale blue flame to yield iodine pentafluoride. The iodine can be in the molten state at high pressure [406] or iodine can be dissolved in iodine pentafluoride and reacted with fluorine to form additional iodine pentafluoride [407]. Iodine pentafluoride can be made by fluorinating iodine pentoxide with carbonyl fluoride [408].

The reaction between I_2O_5 and liquid BrF_3 was found to be a suitable laboratory method for the preparation of IF_5 [409]. The reaction can be performed in a silica flask with no special equipment needed. The yield of the isolated pure IF_5 was 80%.

Likewise, fluorine gas reacts with metallic iodides and hydrogen iodide to produce iodine pentafluoride and the corresponding fluorides. The preparation of small amounts of iodine pentafluoride can be carried out by passing a stream of fluorine over iodine crystals contained in a platinum boat in a glass tube. The iodine pentafluoride can be condensed in a cold trap at the end of the glass tube. At room temperature, iodine pentafluoride is a liquid and iodine heptafluoride is a vapor. Iodine pentafluoride can be distilled at atmospheric pressure without decomposition. When it is heated to approximately 773 K (500 °C), however, iodine vapors are produced.

4.1.2 Physical Properties of Iodine Pentafluoride

The triple point of iodine pentafluoride is $282.553 \pm 0.01 \text{ K}$ [410]. The vapor pressure measured between 283 and 378 K can be represented by the equation:

$$\log_{10} P = -3090.14/T - 6.96834 \log_{10} T + 29.02167$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin.

For additional information on iodine fluorides and other halogen fluorides, see [411–419].

The enthalpy of formation of liquid iodine pentafluoride as determined calorimetrically by direct reaction of the elements was -882.0 ± 1.6 kJ/mol (-210.81 ± 0.39 kcal/mol) [420]. From the same data an enthalpy of formation for gaseous iodine heptafluoride of -961.5 ± 2.1 kJ/mol (-229.8 ± 0.5 kcal/mol) was derived. Thermodynamic properties of IF_5 and IF_7 are compared in Table 40.

Table 40: Thermodynamic properties of iodine fluorides.

Property	SI Units	MKS Units	References
Iodine Pentafluoride			
Enthalpy of formation, gas (ΔH°_{298})	-847.7 kJ/mol	-202.6 kcal/mol	[72]
	-840.31 kJ/mol	-200.8 kcal/mol	[40]
Enthalpy of formation, liquid (ΔH°_{298})	-882.0 ± 1.6 kJ/mol	-210.81 ± 0.39 kcal/mol	[420]
	-881.99 ± 1.34 kJ/mol	-210.80 ± 0.32 kcal/mol	[410]
Heat of fusion	11.222 ± 0.011 kJ/mol	2.682 ± 0.003 kcal/mol	[410]
Heat of evaporation at 330 K	39.32 kJ/mol	9.39 kcal/mol	[410]
Iodine Heptafluoride			
Enthalpy of formation, gas (ΔH°_{298})	-969 kJ/mol	-231.7 kcal/mol	[72]
	-961.06 kJ/mol	-229.7 kcal/mol	[40]
	-961.5 ± 2.1 kJ/mol	-229.8 ± 0.5 kcal/mol	[420]

Raman spectra of iodine pentafluoride have been measured for the gas as well as for the liquid as a function of temperature [421]. An intense polarized band, which appeared in the room temperature spectra of the liquid at 697 cm^{-1} and a weaker, previously unreported, band at 218 cm^{-1} , were absent both from the gas spectra and from the elevated temperature spectra of the liquid. This indicated that these bands arise from the presence of polymers in the liquid state rather than from Fermi resonance.

The rotational constant, quadrupole coupling constant and C_{4v} symmetry of IF_5 were determined from its microwave spectrum [422].

All halogen fluorides are diamagnetic. The average molar magnetic susceptibility of chlorine trifluoride, bromine trifluoride, bromine pentafluoride, and iodine pentafluoride measured at different field strengths is -26.5×10^{-6} c.g.s. units, -33.9×10^{-6} c.g.s. units, -45.1×10^{-6} c.g.s. units and -58.1×10^{-6} c.g.s. units respectively [102].

The crystal structure of solid iodine pentafluoride is monoclinic with $a = 15.07\text{ \AA}$, $b = 6.836\text{ \AA}$, $c = 18.24\text{ \AA} = 92.96$, $Z = 20$, most probable space group $C2/c$ [423]. The molecular dimensions are $\text{I}-\text{F}_{\text{apical}} = 1.74\text{ \AA}$, $\text{I}-\text{F}_{\text{basal}} = 1.87\text{ \AA}$, and $\angle \text{F}-\text{I}-\text{F} = 81.9^\circ$. The molecular structure of IF_5 was compared with that of BrF_3 and BrF_5 [401]. Complete three-dimensional data were recorded at $153\text{ K} = -120^\circ\text{C}$. The crystal system

is monoclinic with $a = 15.16 \text{ \AA}$, $b = 6.86 \text{ \AA}$, $c = 18.20 \text{ \AA}$, $\beta = 93^\circ 14'$, and space group $C_s^4 = C_c$. The density of solid iodine heptafluoride at $273 \text{ K} = 0^\circ \text{C}$ was reported to be 3.754 g/cm^3 . Liquid iodine pentafluoride has a specific conductivity of 2×10^{-5} to $3 \times 10^{-5} \Omega^{-1} \text{ cm}^{-1}$ at 298 K (25°C) and has a positive temperature coefficient [121]. The dielectric constant of liquid IF_5 has been measured in the range 273 to 315 K (0 to 42°C) at several frequencies and may be expressed by the equation [99, 100]:

$$\epsilon = 41.09 - 0.198t$$

where ϵ is the dielectric constant (dimensionless) and t is the temperature in $^\circ \text{C}$. The results indicated that these substances are associated in the liquid state.

The dielectric constant of gaseous IF_5 has been measured in the vapor phase using a refractivity method [101]. The large electric moment of IF_5 excludes the trigonal bipyramidal and pentagonal planar structures. This is in satisfactory agreement with a distorted octahedral arrangement in which the iodine atom is probably below the plane of the four fluorine atoms on the side opposite the fifth fluorine atom, and the unshared pair is in the sixth position.

4.1.3 Chemical Properties of Iodine Pentafluoride

Iodine pentafluoride and iodine heptafluoride are both stable at room temperature. Iodine pentafluoride reacts violently with water and with aqueous solutions in general. Apparently, the hydrolysis proceeds as follows:

Iodine pentafluoride and iodine heptafluoride undergo fluorine exchange reactions with iodine pentafluoride oxide [424].

Similar to chlorine and bromine fluorides, iodine trifluoride and iodine pentafluoride form fluoroiodate and fluoroiodonium(V) salts, which are potentially useful as solid propellant oxidizers or as fluorinating agents [425–428]. Single-crystal XRD studies have shown that the $\text{IF}_5 \cdot \text{SbF}_5$ adduct has the predominantly ionic structure $[\text{IF}_4^+][\text{SbF}_6^-]$. Iodine pentafluoride forms adducts with acetonitrile [429].

4.2 Iodine Heptafluoride

Iodine heptafluoride, IF_7 , CAS RN [16921-96-3] forms colorless crystals, which melt at 277.6 K (4.5°C). The liquid range is extremely narrow, with the boiling point at 277.93 K (4.77°C). The vapor has a moldy, acrid odor. On passing fluorine into liquid iodine pentafluoride at room temperature, no appreciable amount of a more volatile fluoride was obtained, but when a mixture of iodine pentafluoride and fluorine was heated under pressure in an autoclave, iodine heptafluoride was produced [430, 431]. Iodine

heptafluoride is of interest because it is the halogen fluoride with the highest state of oxidation of the central atom.

Over the range 373–543 K (100–270 °C), the yield of iodine heptafluoride based on the fluorine used increased with increasing temperature [432]. Because of the corrosive nature of the reactants, a platinum apparatus had to be used for this reaction. Operating at a temperature of 523–543 K (250–270 °C), 83% of the fluorine used was converted to iodine heptafluoride. The iodine heptafluoride was purified by pumping off silicon tetrafluoride contamination at 183 K (–90 °C), followed by fractional distillation of iodine heptafluoride from the iodine pentafluoride. A frequent contaminant in IF_7 is IOF_5 , which forms by hydrolysis with moisture.

Iodine heptafluoride, as one of the interhalogen compounds, is of chemical interest both of a theoretical and practical nature. It is unique in being the only simple binary compound in which sevenfold coordination is observed, and in common with other halogen fluorides, it is a possible substitute for fluorine in certain fluorination reactions [433]. No stable addition compounds of the type $\text{M}[\text{IF}_8]$ could be obtained from the interaction of iodine heptafluoride and alkali metal fluorides.

Free vapor-phase molecules of iodine heptafluoride are pentagonal bipyramids with axial bonds ($1.786 \pm 0.007 \text{ \AA}$) shorter than equatorial bonds ($1.858 \pm 0.004 \text{ \AA}$) [434]. They are deformed from D_{5h} symmetry on average by 7.5° ring displacements and 4.5° axial bend displacements.

Iodine heptafluoride, the most frequently studied prototype of a heptacoordinated molecule, had presented many mysteries concerning its spectroscopic and structural properties. It was shown by *ab initio* calculations and a reexamination of the vibrational spectra and their normal coordinate analysis that most of the previously implied abnormalities were due to incorrect assignments [435]. All the available structural data for IF_7 are consistent with a dynamically distorted pentagonal bipyramidal molecule with D_{5h} symmetry in the ground state.

A potential function consisting of the ordinary valence force terms and central force terms has been adopted for the evaluation of potential constants for iodine heptafluoride [436].

Similar to other halogen fluorides, iodine heptafluoride forms fluoroiodate and fluoroiodonium(VII) salts, which are potentially useful as solid propellant oxidizers or as fluorinating agents [437–439].

5 Ternary Fluorides

By way of definition, we call “binary fluorides” those that contain only one type of atom that is different from fluorine. Examples are ClF_3 and NF_3 . We call “ternary fluorides” those compounds that contain two different atoms other than fluorine. Examples are ClO_3F and NO_2F .

5.1 Chlorine–Oxygen–Fluorides

Several chlorine–oxygen–fluorine ternary fluoride compounds that contain chlorine, oxygen, and fluorine in one and the same molecule are reported in the literature and at least one of these is of interest as an oxidizer in liquid rocket propellants. The chlorine–oxygen–fluorides are: chlorine dioxygen fluoride, ClO_2F , (also called “chloryl fluoride”) chlorine trioxygen fluoride, ClO_3F , (also called “perchloryl fluoride”), chlorine tetraoxygen fluoride (incorrectly also called “fluorine perchlorate”), ClO_4F , and, finally, chlorine oxygen trifluoride, ClOF_3 , and chlorine dioxygen trifluoride, ClO_2F_3 . Summaries of the literature on chlorine–oxygen–fluorine compounds can be found in [52, 223, 440–442].

Halogen oxyfluorides are prepared by forming either halogen–fluorine or halogen–oxygen bonds. One of the published summaries dealt exclusively with the formation of halogen–halogen bonds, and preparative methods for halogen oxyfluorides based on the formation of halogen–oxygen bonds were not included [443].

5.1.1 Chlorine Dioxygen Fluoride FClO_2 (also called “Chloryl Fluoride”)

Chloryl fluoride, chlorine dioxygen fluoride, FClO_2 , CAS RN [13637-83-7], is the most common chlorine oxide fluoride and is frequently encountered in the reactions of the binary chlorine fluorides ClF , ClF_3 , and ClF_5 with oxides and hydroxides. Chlorine dioxygen fluoride has no practical use as a rocket propellant. It is often encountered as a contaminant or intermediate in the preparation of other chlorine oxygen fluorides. It might be useful as an intermediate in the synthesis of other high-energy oxidizers. Its relative, chlorine trioxygen fluoride ClO_3F , will be discussed in more detail in Section 5.1.2.

5.1.1.1 Preparation of Chlorine Dioxygen Fluoride

Chloryl fluoride is most conveniently prepared in a high yield by the reaction of stoichiometric amounts of NaClO_3 and ClF , yielding NaF , Cl_2 , O_2 , and FClO_2 . The chlorine fluorides ClF , ClF_3 , and ClF_5 when used in excess, also undergo fluorine oxygen exchange reactions with nitrate anion, forming FClO_2 , unstable FCIO , and ClONO_2 re-

spectively as the primary products. Chlorine dioxygen fluoride is formed by the addition of elemental fluorine to chlorine dioxide:

or reaction of gaseous ClO_2 with powdered AgF at 338–343 K (65–70 °C) [444].

The literature methods reported prior to 1975 for the synthesis of FClO_2 were inconvenient, as they either involved the fluorination of shock-sensitive chlorine oxides or, as in the case of the $\text{KClO}_3 + \text{BrF}_3$ reaction, resulted in product mixtures that were difficult to separate. An improved synthesis of FClO_2 from NaClO_3 and ClF_3 is more convenient than the previous literature methods [445]. It is based on the previous observations that gaseous ClF_3 reacts with KClO_3 to produce FClO_2 in a high yield, but it reduces the ClF_3 requirements by 60%. In this method, dry NaClO_3 is combined with approximately an equimolar amount of ClF_3 at 77 K (–196 °C) in a stainless steel cylinder. The mixture is allowed to warm slowly and kept at room temperature for about 1 day. Chloryl fluoride is thus obtained in a high yield according to:

The products condensable at 77 K (–196 °C) can be separated either by fractional distillation or by repeated fractional condensation. The substitution of the previously used KClO_3 by NaClO_3 is significant as KF forms a 1:1 adduct with ClF_3 whereas NaF does not.

Chlorine oxyfluorides can be prepared by the reaction of halogen oxides with elemental fluorine. The interaction of F_2 with chlorine oxides, such as ClO_2 , Cl_2O_6 , or Cl_2O_7 produces FClO_2 . Quantitative yields of FClO_2 are obtained with ClO_2 as a starting material and moderate reaction conditions [446]. Inert solvents, such as CFCl_3 , or diluents, such as air or N_2 , are recommended to avoid hazards due to the explosive nature of the chlorine oxides. For the higher chlorine oxides, the need for elevated temperature and the decreased yields of FClO_2 suggest that the primary step in these reactions might involve the thermal decomposition to ClO_2 , which is then fluorinated. Therefore, all of these reactions are likely to involve the step:

In view of the shock sensitivity of chlorine oxides, none of the above methods is recommended for the large-scale production of FClO_2 , and necessary safety precautions must be used. The recommended method for the preparation of FClO_2 is the reaction of NaClO_3 with ClF_3 .

The risk of explosions in the ClO_2 reactions is reduced when ClO_2 is replaced by the less dangerous Cl_2O . The yield of FClO_2 using this method is 35%. Similarly, Cl_2O can be fluorinated at 195 K (–78 °C) with either ClF_5 :

or ClF_3 :

In these two reactions an unstable FClO molecule is formed as an intermediate, but disproportionates to yield FClO_2 and ClF .

5.1.1.2 Physical Properties of Chlorine Dioxide Fluoride

Chloryl fluoride melts at 158 K (-115°C) and boils at 267 K (-6°C). It is of interest to compare the IR and Raman spectra of the different chlorine-oxygen fluorides, for instance, to compare chloryl fluoride with those of perchloryl fluoride, molecules with different symmetry and bond orders. The IR spectrum of gaseous chloryl fluoride has been examined in detail from 300 to 4000 cm^{-1} and the chlorine and oxygen isotopic structures of many of the fundamental overtone and combination bands have been resolved [447]. The Raman spectrum of liquid chloryl fluoride was also observed from 100 to 1500 cm^{-1} and polarization measurements were taken. All the fundamental frequencies of the molecule were observed and correlated in both the IR and Raman spectra. The strong bands located at 1265, 1104, 627, and 542 cm^{-1} have been assigned to 4 of the 6 fundamental vibrations expected for a pyramidal tetratomic molecule pertaining to the C_8 point group [448].

Additional information on molecular structure and bond constants could be obtained from the microwave spectra of chloryl fluoride [449, 450]. The spectra and kinetics of chloryl fluoride formation and decomposition have been investigated thoroughly because it may play a role in the ozone depletion of the upper atmosphere due to fluorocarbons [451].

An isomer of chloryl fluoride would be chlorine fluoride peroxide, $\text{F}-\text{O}-\text{O}-\text{Cl}$, which has a CAS RN [177778-93-7] number, but its existence is unlikely.

5.1.1.3 Chemical Properties of Chlorine Dioxide Fluoride

Although FClO_3 does not react with LiNO_3 at temperatures as high as 348 K (75°C), FClO_2 reacts with LiNO_3 or N_2O to give ClONO_2 and O_2 in a high yield. Chlorine nitrate slowly reacts with ClF to give NO_2F and Cl_2O as the primary products and a side reaction of Cl_2O with ClF gives Cl_2 and goes back to more FClO_2 .

Complex Salt Formation with Chlorine Dioxide Fluoride

Salts of the $[\text{ClO}_2^+]$ cation are also called chloronium salts. They may be useful as oxidizers in solid propellants with perfluorinated polymers as binders. The 1:1 adducts $\text{ClO}_2\text{F}\cdot\text{AsF}_5$ and $\text{ClO}_2\text{F}\cdot\text{BF}_3$ have been investigated [452, 453]. Whereas $\text{ClO}_2\text{F}\cdot\text{AsF}_5$ is stable at ambient temperature, the $\text{ClO}_2\text{F}\cdot\text{BF}_3$ adduct showed a dissociation pressure of 30.39 kPa at 298 K (228 mm Hg at 25°C). A pressure-temperature curve gave a heat of reaction of 100.5 kJ/mol (24.0 kcal/mol) for the dissociation process:

The XRD patterns of $\text{ClO}_2\text{F}\bullet\text{AsF}_5$ and $\text{ClF}_3\bullet\text{AsF}_5$ were recorded and indexed. Infrared and Raman measurements showed that $\text{ClO}_2\text{F}\bullet\text{AsF}_5$ and $\text{ClO}_2\text{F}\bullet\text{BF}_3$ have the ionic structures $[\text{ClO}_2^+][\text{AsF}_6^-]$ and $[\text{ClO}_2^+][\text{BF}_4^-]$ respectively in the solid state. All fundamental vibrations were observed and a valence force field was calculated for ClO_2^+ .

The infrared and Raman spectra of chloryl hexafluoroarsenate were obtained [454]. The observed vibrations were interpreted in terms of an ionic compound $[\text{ClO}_2^+][\text{AsF}_6^-]$, where strong cation–anion interaction results in a symmetry lowering of the AsF_6^- ion.

5.1.2 Chlorine Trioxxygen Fluoride ClO_3F (Also Called “Perchloryl Fluoride”)

Next to chlorine trifluoride and chlorine pentafluoride, among all the non-metallic fluorides, perchloryl fluoride (chlorine trioxxygen fluoride) has received the most attention from rocket propellant chemists as a potential high-energy oxidizer for liquid rocket applications. We use the two names for this chemical here interchangeably.

5.1.2.1 Preparation of Chlorine Trioxxygen Fluoride

Chlorine trioxxygen fluoride, ClO_3F , perchloryl fluoride (also called “Florox”), CAS RN [7616-94-6], was discovered in 1952 by electrolysis of perchloric acid in H_2F_2 solution [455]. Instead of perchloric acid, similar results are obtained when electrolyzing potassium perchlorate in H_2F_2 [456]. With a formula mass of $M = 102.45 \text{ g/mol}$, it contains 46.85 mass-% O, 34.61 mass-% Cl, and 18.54 mass-% F.

A simple method for making perchloryl fluoride is by reaction of potassium perchlorate with fluorosulfonic acid (fluorosulfuric acid, sulfurofluoridic acid) [457]:

Both reagents are readily available. This method is even suitable for the preparation of small quantities of ClO_3F in the laboratory [458–461].

Perchloryl fluoride can also be made by reaction of perchlorates in H_2F_2 solution with SbF_5 :

Whereas fluorination of halogen oxyacids can result in the formation of the corresponding fluorooxy compounds:

fluorination of the salts of these halogen oxyacids is a more useful method for the synthesis of halogen oxyfluorides [443]. The nature of the halogen oxyfluoride product depends on the starting material and the reaction conditions. Thus, the fluorination of perchlorates is a high-yield synthesis of perchloryl fluoride. Perchloryl fluoride can also be prepared by heating potassium perchlorate with antimony pentafluoride in a high-pressure bomb. Heating of KClO_4 to 973–1473 K (700–1200 °C) in an excess

of SbF_5 produces FClO_3 in a 50% yield [462]. The yield of FClO_3 can be increased to 90% and the reaction temperature can be lowered to 473–773 K (200–500 °C), when a mixture of HF with SbF_5 is used instead. Slightly lower yields are obtained when the HF solvent is replaced by AsF_3 , IF_5 , or BrF_5 .

Most of the commercial processes are based on the use of HOSO_2F as the fluorinating agent for KClO_4 . Evolution of FClO_3 starts at 323 K (50 °C) and goes to completion at 1123–1373 K (850–1100 °C). The yields of FClO_3 vary from 50 to 80% and, if necessary, the HOSO_2F can be regenerated. The addition of certain additives such as 5 to 25% SbF_3 to the HOSO_2F increased the yield of FClO_3 to 90%, but hindered the regeneration of HOSO_2F . Better yields were possible by the addition of BF_3 , SbF_3 , or HF [463]. The addition of HF/ BF_3 increased the FClO_3 yield to 85%, but required elevated pressure. The highest yield of perchloryl fluoride (97%) was achieved with a mixture of fluorosulfonic acid and SbF_5 as fluorinating medium. Potassium, sodium, lithium, magnesium, barium, calcium, and silver perchlorates and perchloric acid itself undergo the reaction, but most of the time KClO_4 is used [464]. See also [465].

Perchloryl fluoride ClO_3F and other halogen trioxygen fluorides can be prepared by a continuous process gas–liquid reaction by passing a mixture of ClF or ClF_3 with F_2 through an aqueous solution of HF, KF, NaF, KOH, NaOH, or K_2CO_3 [466].

5.1.2.2 Physical Properties of Chlorine Trioxygen Fluoride

The physical properties of ClO_3F are summarized in Table 41.

Table 41: Physical properties of chlorine trioxygen fluoride.

Property	SI Units	MKS Units	Authors	Year	References
Molecular mass	102.5				
Melting point	127 ± 2 K	-146 ± 2 °C	Pennsalt	1957	[467]

The density of perchloryl fluoride as a function of temperature can be calculated by the equation [469]:

$$\rho = 2.266 - 1.603 \times 10^{-3} T - 4.080 \times 10^{-6} T^2$$

where ρ is the density in g/cm³ and T is the temperature in kelvin. Data obtained with this equation are illustrated in Figure 44.

Figure 44: Density of perchloryl fluoride. (Chart created by Schmidt 2016, based on data from [469].)

See also [473]. The heat capacity and several other physical properties of perchloryl fluoride have been measured from 15 to 225 K [468]. The heat of fusion was found to be 3.834 kJ/mol (916.3 cal/mol) at melting point, which was determined as 125.41 K = -147.74°C . The heat of evaporation was determined calorimetrically to be 19.32 kJ/mol (4.619 kcal/mol) at boiling point, which is at 226.48 K = -46.67°C . The vapor pressure was measured and the data are represented by the equation

$$\log P = -1652.37/T - 8.62625 \log T + 0.0046098T + 28.44780$$

where P is the vapor pressure cm Hg (not mm Hg!) and T is the temperature in kelvin. Other investigators found the equation for the vapor pressure curve of ClO_3F to be

$$\log P = 7.683 - 1083.8/T$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin. A boiling point of 225.6 K = -47.5°C was calculated from this equation.

More accurate vapor pressures can be obtained from the following two equations. One equation is applicable to the temperature range 131 to 234 K (-142 to -39°C) and the other is applicable to the temperature range from the normal boiling point (234 K) to the critical point at 368 K [469]

$$\log P = 18.90112 - 1443.967/T - 4.09566 \log T$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin and

$$\log P = 4.46862 - 1010.81/T$$

where P is the vapor pressure in atm and T is the temperature in kelvin. A comparison of the Jarry and Koehler/Giauque vapor pressure equations shows that the two curves falls virtually on top of each other and agree totally (Figure 45).

Figure 45: Comparison of perchloryl fluoride vapor pressure data in the low temperature range from two different sources.

The vapor pressure data for the high pressure range from the normal boiling point at 234 K to the critical point at 368 K are illustrated in Figure 46.

Figure 46: Vapor pressure of perchloryl fluoride for the high pressure range from the normal boiling point to the critical point.

The viscosity of liquid perchloryl fluoride can be calculated from the following equation [470]:

$$\log \eta = 299/T - 1.755$$

where η is the viscosity in centiPoise and T is the temperature in kelvin.

Optical Properties of Chlorine Trioxygen Fluoride

Strong optically pumped laser action has been obtained in perchloryl fluoride, excited by a CO₂ laser [474]. Thirty-four new lines were observed between 16.3 and 17.7 μm , with outputs of up to 4 mJ.

Infrared Spectra of Chlorine Trioxygen Fluoride

Infrared spectra of perchloryl fluoride have been used in determining the molecular structure of the molecule and for quality control to identify contaminants in the product. The IR spectrum of ClO₃F was determined between 525 and 625 cm⁻¹ and supported the structure of a symmetric top-shaped molecule [475].

The IR spectrum of gaseous ClO₃F was obtained over the range 3–43 μm [476]. Satisfactory assignments of absorption bands were achieved on the basis of a C_{3v} model in which the four peripheral atoms are each bonded to the central chlorine (Table 42). The stability of the C_{3v} structure for ClO₃F was compared with that of ClO₄⁻ and similar molecules.

Table 42: Infrared band assignments for gaseous perchloryl fluoride.

Wave number, cm ⁻¹	Species group	Designation	Vibration type
1061	A ₁	ν_1	Cl—O stretching
715	A ₁	ν_2	Cl—F stretching
549	A ₁	ν_3	ClO ₃ bending
1315	E	ν_4	Cl—O stretching
589	E	ν_5	ClO ₃ bending
405	E	ν_6	Rocking

Data source: [476]

The intensities of the IR absorption spectrum of FClO₃ in the gas phase, as shown in Figure 47 and Table 43, have been used to calculate the force field and the bond strengths of the FClO₃ molecule [477]. Possible versions of the force constant matrix and the dependence of the forms of the vibration on the choice of force field have been analyzed. The electron density distribution has been estimated by a semi-empirical quantum-chemical method. The FClO₃ molecule has a dipole moment of 0.023–0.025 D. On the basis of a simple vector model, it is possible to find the ratio between the dipole moments of the bonds 0.024. This corresponds to an unusual situation in

Table 43: Intensities of the IR absorption bands of perchloryl fluoride.

Band assignment (Species)	Wavenumber, cm^{-1}	Absorption coefficient, $\text{L mol}^{-1} \text{cm}^{-2} \times 10^{-3}$
$\nu_1(\text{A}_1)$	1060	2.05
$\nu'_2(\text{A}_1)$	715 and 705	7.08
$\nu_2(\text{A}_1)$	550	2.3
$\nu_4(\text{E})$	1317	19.4
$\nu_5(\text{E})$	589	2.03
$\nu_6(\text{E})$	405	0.44

Data source: [477]

which the effective charge on the strongly electronegative fluorine atom is less than (or equal to) the effective charge on the oxygen atom. An attempt was made to analyze the electron density distribution from the intensities of the infrared spectra of FClO_3 and by quantum-chemical calculation.

The IR spectrum of isotope-labeled $\text{FCl}^{18}\text{O}_3$ has been recorded in the 610–1170 cm^{-1} range, using a Fourier transform infrared (FTIR) spectrometer with a resolution of 0.0024 cm^{-1} [478]. The ν_1 and ν_2 parallel bands (with band centers at 1011.1 and 708.2 cm^{-1} for the $\text{F}^{35}\text{Cl}^{18}\text{O}_3$ isotopomer and 1007.5 and 699.3 cm^{-1} for the $\text{F}^{37}\text{Cl}^{18}\text{O}_3$ isotopomer) have been studied and their resolved J and K structures have been analyzed. A set of accurate molecular constants has been determined for the ground state and $\nu_1 = 1$ and $\nu_2 = 1$ excited states of both isotopic species, which reproduced approximately 9700 observed lines with a standard deviation of $\approx 1 \times 10^{-4} \text{ cm}^{-1}$.

The high-resolution IR spectra of monoisotopic $\text{F}^{35}\text{Cl}^{18}\text{O}_3$ and $\text{F}^{37}\text{Cl}^{18}\text{O}_3$ have been studied in the region of the ν_4 fundamentals, centered at 1278.3 and 1263.3 cm^{-1} respectively [479]. Large perturbations were observed in both bands owing to a Fermi-type anharmonic resonance with the $\nu_2 + \nu_5$ combination bands, centered at 1270.7 cm^{-1} in $\text{F}^{35}\text{Cl}^{18}\text{O}_3$ and 1257.3 cm^{-1} in $\text{F}^{37}\text{Cl}^{18}\text{O}_3$. A comparison of measured high-resolution FTIR spectra of perchloryl fluoride and predictions using high-level *ab initio* methods gave fairly good agreement [480]. The geometry, dipole moment, and anharmonic force field of the molecule have also been calculated using *ab initio* methods. In continuation of this work, the high-resolution infrared spectra of isotope-labeled monoisotopic $\text{F}^{35}\text{Cl}^{16}\text{O}_3$, $\text{F}^{37}\text{Cl}^{16}\text{O}_3$, $\text{F}^{35}\text{Cl}^{18}\text{O}_3$, and $\text{F}^{37}\text{Cl}^{18}\text{O}_3$ have been studied in the region of the $2\nu_5$ overtones, from 1100 to 1200 cm^{-1} [481]. Both the parallel $2\nu_5^\circ$ and the perpendicular $2\nu_5^{\pm 2}$ components were clearly observed in the spectra, their origins differing by about 0.4 cm^{-1} . In each spectrum about 2000 transitions have been assigned, 35% of them belonging to $2\nu_5^\circ$.

Raman Spectra of Chlorine Trioxxygen Fluoride

Raman spectra of gaseous ClO_3F (Table 44) confirmed the earlier proposed tetrahedral C_{3v} symmetry [482].

Table 44: Raman spectra band assignments of gaseous perchloryl fluoride.

Raman wave numbers, cm^{-1}	Corresponding IR fundamental, cm^{-1}	Vibration	Species group	Assignments
410 m	405	6	E	rocking
549 ms	549	3	A_1	bending
587 m	589	5	E	bending
695–724 m	704	2	A_1	stretching ^{37}ClF
	714	2	A_1	stretching ^{35}ClF
1601 s	1061	1	A_1	Cl–O stretching
1175 w (broad)				2×587 (E) = 1174 ($A_1 + E$)
1312 w (broad)	1315	4	E	Cl–O stretching
1346 w				
1460 (broad)				$1060 + 410 = 1471$ (E)

s = strong, ms = medium strong, m = medium, w = weak

Data source: [482]

In agreement with the earlier assignments, bands at 1062, 716, and 549 cm^{-1} were again assigned to A_1 and the 1314, 573, and 414 cm^{-1} bands were assigned to E for tetrahedral C_{3v} symmetry [483]. In the liquid an unexpectedly broad band was observed between 695 and 724 cm^{-1} , whereas in the gas phase this band was resolved to show the isotope shift.

The contour of the ν_6 (E) Raman band of liquid ClO_3F has been studied over the temperature range 133–350 K [484]. Isotope splitting, vibrational, and instrumental influences on the band shapes were taken into account, and reorientational and angular momentum correlation times were obtained by comparing the corrected Fourier transforms of the band contours with the reorientational correlation functions calculated using the J -diffusion limit of the extended rotational diffusion model. The spinning top shape of the ClO_3F molecule is a good subject for such studies.

Microwave Spectra of Chlorine Trioxxygen Fluoride

As a result of the unsuccessful search for a microwave spectrum, it was concluded that the dipole moment of ClO_3F must be very small, not more than 0.09 D [485].

The millimeter-wave spectrum of natural FClO_3 has been recorded in the 350–400 GHz range, and transitions with $33 \leq J \leq 37$ and $0 \leq K \leq 30$ have been measured [486]. For comparison, the IR spectrum of monoisotopic $\text{F}^{35}\text{ClO}_3$ has been investigated in the 350–800 cm^{-1} region with a resolution of $3\text{--}4 \times 10^{-3} \text{ cm}^{-1}$, and the fundamentals ν_2 , ν_3 , ν_5 , and ν_6 were rotationally resolved. The ground state constants B_0 , DJ_0 , and DJK_0 were obtained by combining microwave and millimeter-wave data and ground-state combination differences determined from the ν_2 and ν_5 infrared bands. Equilibrium rotational constants of $\text{F}^{35}\text{ClO}_3$ were deduced with the help of vibrational corrections and the structure of FClO_3 was determined more accurately than before.

^{18}O -enriched, monolabeled perchloryl fluoride, $^{19}\text{F}^{35/37}\text{Cl}^{16}\text{O}^{18}\text{O}_2$, has been synthesized and its rotational microwave spectrum was recorded in the 4–22 GHz region [487]. For comparison, the spectra of the symmetric isotopomers $^{19}\text{F}^{35/37}\text{Cl}^{16}\text{O}_3$ were reinvestigated. Rotational and centrifugal distortion constants, as well as chlorine nuclear quadrupole and chlorine and fluorine spin–rotation and spin–spin coupling constants were then determined for the ground vibrational state and gave geometrical parameters and harmonic force field data.

Electric Properties of Chlorine Trioxxygen Fluoride

Dipole moments derived from the measurement of non-resonant dielectric loss of perchloryl fluoride gave a very small dipole moment of 0.023 D [488].

Perchloryl fluoride possesses one of the lowest molecular electric dipole moments, yet the solid exhibits appreciable dielectric absorption with maxima at low temperatures (90–110 K) and 500 Hz to 200 kHz frequencies from a Debye relaxation process [489, 490]. The dielectric properties and activation energy of 24.8 kJ/mol for molecular reorientation are somewhat unusual for a rotator solid and were discussed in terms of free-volume theory. In the clathrate hydrate condition there was no apparent dielectric dispersion from orientation of the guest ClO_3F , although the temperature dependence of the dielectric permittivity suggested possible contributions from dipole rotations and lattice vibrations at low temperatures.

The dipole moment of ClO_3F in solution was quite different from that in the vapor phase [491].

Magnetic Properties of Chlorine Trioxxygen Fluoride

When a nucleus of non-zero spin is bonded directly, or with a few intervening atoms, to another nucleus of nonzero spin, coupling of the two nuclear spins occurs via the bonding electrons. If the spin-coupled nuclei are magnetically non-equivalent, the spin coupling manifests by a splitting of the observed nuclear resonance peaks. When a nucleus of spin $1/2$ is coupled with a nucleus with spin greater than $1/2$, spin coupling is not always observed in the resonance spectrum of the nucleus with spin $1/2$. This can be attributed to a rapid relaxation of the nucleus with spin greater than $1/2$ owing to interaction of its quadrupole moment with an unsymmetrical electric field gradient. One would expect to see spin coupling when there is spherical symmetry about the nucleus of spin greater than one half, and this is observed. If the symmetry is less, the individual lines broaden and eventually coalesce into a single sharp line when the relaxation is rapid. Prior to this work, no examples had been reported of observable spin coupling of nuclei with chlorine, but sharp single peaks were observed. Both chlorine-35 and chlorine-37 have spin $3/2$ and appreciable quadrupole moments. As chlorine is quite electronegative, unsymmetrical bonds are to be expected in most of its compounds and rapid relaxation of the chlorine nuclear spin should occur. The first instance of observable spin–spin coupling with a chlorine nucleus was found in the fluorine resonance of perchloryl fluoride [492]. The lines of perchloryl fluoride had a width of 430 cycles, whereas at the same sweep rate the resonance of trifluoroacetic acid was immeasurably narrow. Therefore, considerable broadening of the fluorine resonance is occurring owing to rapid relaxation of the chlorine nuclear spin, which needed to be explained.

Pulsed ^{19}F NMR studies of spin–lattice relaxation times of solid ClO_3F gave a single reorientational correlation time with an activation energy of 28.9 kJ/mol (6.9 kcal/mol), an energy so high as to suggest that the residual entropy is due to the “freezing-in” of orientational disorder [493]. The low-temperature ^{19}F line shape yielded a chemical shift anisotropy of 570 ± 20 ppm.

Molecular Structure of Chlorine Trioxxygen Fluoride

Chlorine trioxxygen fluoride is thermally stable up to $\sim 723\text{ K}$ ($\sim 450^\circ\text{C}$). The thermal stability is believed to be due to the high symmetry of the molecule. Chlorine trioxxygen fluoride has a tetrahedral structure with the chlorine atom in the center and the oxygens and the fluorine at the corners of the tetrahedron (Figure 48). The fluorine atom is bonded directly to the central chlorine atom and does not attach to an $-\text{O}-\text{F}$ linkage.

The bond lengths are: $\text{F}-\text{Cl}$ 1.63 Å, $\text{O}-\text{Cl}$ 1.48 Å, $\angle\text{F}-\text{Cl}-\text{O}$ $95^\circ 10'$, $\angle\text{O}-\text{Cl}-\text{O}$ $119^\circ 12'$. The XRD powder diffraction pattern and the density of solid ClO_3F have been determined at liquid air temperatures [494]. From the powder data it appears that crystalline ClO_3F is tetragonal.

In several studies the FClO_3 molecule had been used as a model compound to test the validity of bond strength and force field calculations. The IR spectra of frozen FClO_3 in Ne, N_2 , and Ar matrices were recorded and the ^{35}Cl – ^{37}Cl isotopic shifts were

Figure 48: Molecular structures of chlorine trioxxygen fluoride.

measured to calculate bond strengths and force fields [495]. The Coriolis constants of the E-species vibrations were redetermined and, together with the isotopic data, used for the computation of a general valence force field. The A_1 block, for which only isotopic frequencies were available, was fixed with the help of *ab initio* force constant calculations. It was shown that ν_2 and ν_3 would best be described as an anti-symmetric and a symmetric combination respectively of the Cl—F stretching and the ClO_3 bending motions. Comparison with 13 previously published force fields demonstrated the inadequacy of undetermined force fields for strongly coupled systems, such as FCIO_3 . The ClO and ClF stretching force constants were found to be 9.76 and 3.49 mdyne $\text{\AA}^{-1}$ respectively, in good agreement with those expected for mainly covalent Cl—F single and Cl=O double bonds.

Miscibility of Chlorine Trioxxygen Fluoride

Liquid ClO_3F in a molar ratio of 1:1 is completely miscible with O_2F_2 at 127 K, ClF at 160 K, or ClF_3 at 195 K, but forms two separate layers with LOX at 90 K [41].

Thermodynamic Properties of Chlorine Trioxxygen Fluoride

A standard enthalpy of formation for perchloryl fluoride of -22.6 ± 1.0 kJ/mol was determined from its heat of alkaline hydrolysis measured in a calorimeter, which compared well with a previously obtained value of -26.5 ± 2.9 kJ/mol from the heat of hydrogenation [496]. The thermochemistry of hydrolysis and bond fission of perchloryl fluoride helps to explain its reactivity.

The NIST Chemistry WebBook lists the enthalpy and entropy of formation of the gas as $\Delta H_f^\circ_{\text{gas}} = -21.42$ kJ/mol and $S^\circ_{\text{gas}, 1 \text{ bar}} = 278.97$ J $\text{mol}^{-1} \text{K}^{-1}$ [40]. The JANAF Tables list the enthalpy of formation of the gas as $\Delta H_f^\circ_{\text{gas}} = -5.12 \pm 0.68$ kcal/mol ($= -21.42 \pm 2.84$ kJ/mol) [77]. The gas phase heat capacity of ClO_3F can be expressed by a Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + E/\tau^2$$

where C_p is the heat capacity in $\text{J mol}^{-1} \text{K}^{-1}$ and τ is the absolute temperature in kelvin divided by 1000. The constants A through E are listed in Table 45 for two temperature ranges and are also used to calculate the enthalpy and entropy.

Table 45: Constants for heat capacity, enthalpy, and entropy of chlorine trioxide fluoride vapor.

Temperature range, K	298–1200	1200–6000
A	36.66519	107.0485
B	152.4842	0.561539
C	-125.8631	-0.110696
D	37.21241	0.007508
E	-0.625788	-7.743538
F	-40.19443	-74.34382
G	279.6280	377.5227
H	-21.42204	-21.42204

Data source: [40]

The differential enthalpy of formation of gaseous ClO_3F can be expressed by a polynomial equation

$$H^\circ - H^\circ_{298.15} = A\tau + B\tau^2/2 + C\tau^3/3 + D\tau^4/4 - E/\tau + F - H$$

where $H^\circ - H^\circ_{298.15}$ is the differential enthalpy of formation in kilojoules per mol and τ is the absolute temperature in kelvin divided by 1000. The constants A through H are listed in Table 45 for two temperature ranges and are also used to calculate the heat capacity and entropy.

The entropy of formation of gaseous ClO_3F can be expressed by a polynomial equation

$$S^\circ = A \ln(\tau) + B\tau + C\tau^2/2 + D\tau^3/3 - E/(2\tau^2) + G$$

where S° is the entropy in $\text{J mol}^{-1} \text{K}^{-1}$ and τ is the absolute temperature in kelvin divided by 1000. The constants A through G are listed in Table 45 for two temperature ranges and are also used to calculate the enthalpy and heat capacity.

The heat of formation of gaseous perchloryl fluoride was determined by reacting it with hydrogen in a calorimeter bomb and was calculated as $-21.44 \pm 2.85 \text{ kJ/mol} = -5.12 \pm 0.68 \text{ kcal/mol}$ [471].

The heat capacity of solid perchloryl fluoride was measured over the range $2.7 \text{ K} < T < 23 \text{ K}$ [497]. Analysis of the data showed that only lattice vibrations were contributing to the heat capacity below 12.5 K and that a Schottky anomaly was not present down to 2.7 K. The dielectric constant ϵ of ClO_3F has been measured over the range $4.2 \text{ K} < T < 160 \text{ K}$ with an estimated precision of $\pm 1\%$. A rise in ϵ was observed between 80 K and the melting point at 125.64 K. This behavior may be explained

in terms of molar polarization. A correlation of residual entropy with the Raman spectrum of polycrystalline ClO_3F indicated a partially ordered crystal at 0 K.

Additional physical and thermodynamic data on ClO_3F and other fluorine compounds can be found in [498]. See also [499].

5.1.2.3 Chemical Properties of Chlorine Trioxxygen Fluoride

Thermal Decomposition of Chlorine Trioxxygen Fluoride

Chlorine trioxxygen fluoride is thermally very stable; it decomposes only above 773 K (500 °C) [500–502]. Perchloryl fluoride is thermally stable up to 723 K (450 °C).

Reactions of Chlorine Trioxxygen Fluoride

Reactions with Inorganic Compounds

Activated charcoal ignites in ClO_3F even at very low temperatures (195 K = –78 °C).

Chlorine trioxxygen fluoride is highly resistant to hydrolysis because even at 523–573 K (250–300 °C) the reaction is slow. Rapid hydrolysis, however, can be effected by the use of alcoholic potassium hydroxide at 298 K (25 °C) or hot potassium hydroxide aqueous solutions. Indeed, this reaction may be used to determine perchloryl fluoride quantitatively because a quantitative precipitation of potassium perchlorate takes place whereas potassium fluoride remains in solution.

When dissolved in water, perchloryl fluoride reacted only very slowly with the solvent [503]. The solubility in water at 1 atm and temperatures up to 313 K (40 °C) is given by the equation

$$S = 6.387 \times 10^{-8} \exp(6852/RT)$$

where S is the solubility in mol/L solvent, and T is the temperature in kelvin. The following reactions have been studied to learn their rate laws and rate constants:

At temperatures near 273 K (0 °C), perchloryl fluoride and water readily formed a solid clathrate hydrate of variable composition. The observed minimum ratio of H_2O to ClO_3F in the solid was about 7.75.

Perchloryl fluoride oxidized potassium iodide solution to give elemental iodine and chloride and fluoride ions. With anhydrous ammonia, two liquid phases were formed and a slow reaction took place with the formation of a mixture of ammonium fluoride NH_4F and an ammonium salt of the amide of perchloric acid, $[\text{NH}_4^+] \cdot [\text{HNCLO}_3^-]$ [504]. This ammonium salt formed a stable aqueous solution from which the slightly soluble silver or barium salts of the amide can be precipitated.

These salts are explosive, white crystalline solids. Ammonolysis of ClO_3F in liquid NH_3 was greatly accelerated by traces of NaNH_2 (base catalysis).

Perchloryl fluoride was inert toward AsF_5 and SbF_5 , but the analog bromine compound BrO_3F underwent fluoride ion abstraction and O_2 elimination to form $[\text{BrO}_2][\text{SbF}_6]$, rather than simple fluoride ion abstraction to form BrO_3^+ salts. The reaction of FClO_3 with PtF_6 yielded a product containing $[\text{ClO}_2\text{F}_2^+][\text{PtF}_6^-]$. A synthetic method converted this salt into $[\text{ClO}_2\text{F}_2^+][\text{BF}_4^-]$ or $[\text{ClO}_2\text{F}_2^+][\text{AsF}_6^-]$ [505, 506]. All three salts were stable at 298 K (25 °C), reacted violently with water or organic materials and according to their IR, Raman NMR spectra are ionic in both the solid state and HF solution. The PtF_6^- compound was canary yellow, whereas those of AsF_6^- and BF_4^- were white. It is unlikely that any of these salts can be used as rocket propellants, but they add to the large number of fluorine compounds that could potentially give a very high specific impulse.

The reaction of NH_2OH with ClO_3F did not give new difluoroamino compounds (maybe HONF_2 ??), but instead NH_2OH reacted with ClO_3F to form $(\text{NH}_3\text{OH})\text{F}$ and unstable $(\text{NH}_3\text{OH})\text{ClO}_3$. $(\text{NH}_3\text{OH})\text{ClO}_3$ decomposed to $(\text{NH}_3\text{OH})\text{NO}_3$ and ClO_2 [507].

Reactions with Organic Compounds

Chlorine trioxxygen fluoride is a strong oxidizer, but in contrast to chlorine trifluoride it does not ignite common fuels on contact at room temperature. Mixtures of ClO_3F with combustible gases such as propane or hydrogen burn with potentially explosive power once they are ignited by an external source of energy.

The reaction of ClO_3F with guanidine in solution did not give *N*-fluoro or *N,N'*-difluoroguanidine, but instead yielded guanidinium salts $\text{C}(\text{NH}_2)_3^+\text{X}^-$ ($\text{X} = \text{F}, \text{ClO}_4$) [508, 509].

Chlorine trioxxygen fluoride can be used for the selective fluorination or perchlorylation of organic compounds [510]. However, when insufficiently diluted or in a situation where heat accumulates and is not conducted away fast enough, explosions can occur [511].

Surprisingly, perchloryl fluoride can be dissolved in several organic solvents without instant inflammation. The solutions may be detonable, though. The solubility of perchloryl fluoride in several organic solvents was determined at 298 K (25 °C) and 13–101 kPa (100–760 mm Hg) [512]. ClO_3F was gradually fed from the glass reservoir into an ampule immersed in a temperature-controlled bath. After the attainment of equilibrium, the amount of dissolved ClO_3F was estimated as the difference between the amount of ClO_3F brought into the measuring part of the apparatus and the amount of ClO_3F in the gas phase. The solubility of ClO_3F obeyed Henry's law. For the following solvents, the solubilities at 101 kPa (760 mm Hg) in g ClO_3F /L of the solvent and Henry's law coefficients (ClO_3F partial pressure in the gas phase/ ClO_3F concentration in the liquid phase, in mm Hg/mol fraction) were: tetrahydrofuran 52.4, 14760; dimethoxyethane 44.4, 15950; CCl_4 39.3, 18130; Me_2CO 35.1, 22100; diethylene glycol

dimethyl ether 20.6, 27390; 2-methoxyethanol 22.8, 42940; dimethylformamide 19.3, 52910; MeOH 24.7, 65240; acetonitrile 17.9, 73600.

Analysis of Chlorine Trioxxygen Fluoride

Analytical methods are available to analyze traces of perchloryl fluoride in the work-room air and methods for quality control of perchloryl fluoride analyze for assay and contaminants.

Mass Spectrometric Analysis of Chlorine Trioxxygen Fluoride

In the inlet to a mass spectrometer, perchloryl fluoride is ionized and dissociated by electron impact [513]. Mass spectrometry can also be used to identify the decomposition products of perchloryl fluoride [514]. By this method, the bond energies $F-ClO$, $Cl-OF$, $O-ClF$, $O-ClOF$, and $O-ClO_2F$ have been calculated.

5.1.2.4 Handling of Chlorine Trioxxygen Fluoride

Chlorine trioxxygen fluoride is not as reactive as ClF_3 , but nevertheless many safety precautions need to be taken before using large quantities of it as a rocket propellant. Just as with other fluorine oxidizers, contact with organic lubricants or other combustible materials (rubber, paper) must be avoided.

5.1.2.5 Materials of Construction for Chlorine Trioxxygen Fluoride

Although it hydrolyzes only very slowly, in the presence of water perchloryl fluoride becomes more corrosive.

Compatibility of Chlorine Trioxxygen Fluoride with Metals

Some stainless steels and nickel alloys are resistant even toward moist ClO_3F , but it is recommended to subject them to a passivation period with dry ClO_3F before putting the system into service.

In most cases, Monel and nickel would be the preferred materials of construction. Aluminum, copper, magnesium, titanium, niobium (=columbium), and molybdenum and their alloys and several stainless steels have been investigated with regard to their resistance against chlorine trifluoride and perchloryl fluoride. Most metals (aluminum, copper, nickel, steel, brass, bronze, and Monel) are compatible with dry ClO_3F at room temperature. However, in the presence of traces of moisture the rate of corrosion can become troublesome [515]. Materials compatibility studies were carried out for ClF_3 , ClO_3F , and mixtures of these two oxidizers [198]. A few aluminum, copper, magnesium alloys, and stainless steel with low carbon content were found to be suitable for ClF_3/ClO_3F service, but only for temperatures up to 303 K (30 °C). In all cases, freshly machined metal surfaces have to be slowly passivated with gaseous ClF_3 before they are placed into service at full pressure. Typical alloys of Al, Cu, Mg, Ni, low-carbon steel, and stainless steel were resistant to ClF_3 or ClO_3F and their mix-

tures at 303 K and even under severe mechanical shock [199, 200]. The metals must be clean and dry, but no special passivation was required. An HNO_3/HF pickling acid cleaning step was recommended for stainless steels and high-Ni alloys. Ti, Nb, Mo, and graphite were rapidly attacked by ClF_3 , Ti and ClO_3F , although non-reactive under stagnant conditions at room temperature, were shock sensitive.

Compatibility of Chlorine Trioxygen Fluoride with Non-metallic Materials

Only PTFE (Teflon) and similar perhalogenated gasket materials and lubricants (Kel-F, Permatex) can be used for service with ClO_3F .

Poly(tetrafluoroethylene) and poly(chlorotrifluoroethylene) can be used with ClF_3 or ClO_3F and their mixtures at up to 303 K but mechanical shock must be avoided [199, 200]. Both plastics absorb moderate amounts of the oxidizers and can undergo structural changes and embrittlement. These plastics are best used only in the vapor phase with these gases. They should never be used with these oxidizers under heat, shock, or fast flow conditions.

Fluorocarbon plastics and silicone rubber are suitable for use with OF_2 , and Teflon, polyethylene, and ethylene propylene rubber are suitable for use with a perchloryl fluoride/tetrafluorohydrazine mixture [516].

5.1.2.6 Toxic Properties of Chlorine Trioxygen Fluoride

Small concentrations of chlorine trioxygen fluoride in air can be recognized by their pungent odor at concentrations below the maximum allowable concentration. In 1968, the TLV listed for perchloryl fluoride was 10 ppm. The 2005 NIOSH TWA for perchloryl fluoride was 3 ppm with a short-term ceiling of 6 ppm. The OSHA PEL was 3 ppm. As of 2014, the IDLH value established for perchloryl fluoride by NIOSH [517] was 100 ppm, which had been revised downward from a former level of 385 ppm.

Laboratory animals were exposed to perchloryl fluoride gas for 4 h [518]. Exposures of dogs and rodents to concentrations ranging from 220 to 885 ppm and repeated exposures (6 h/day, 5 days/week) of rodents to 185 ppm for 7 weeks caused pulmonary irritation and increased methemoglobin formation and red blood cell destruction. The 4-h LC_{50} for rats was 385 ppm and for mice 630 ppm. These changes were less severe in rodents exposed repeatedly (6 h/day, 5 days/week) to 104 ppm for 5 weeks. Urinary excretion and bone deposition of fluoride were found in rodents exposed repeatedly to the 185 ppm and 104 ppm levels and in rodents and dogs exposed (6 h/day, 5 days/week) to 24 ppm of perchloryl fluoride for 26 weeks. Urinary fluoride levels decreased very rapidly when exposures were terminated. Fluoride deposition occurred in the bones at a decreasing rate; removal from the bones was very slow after exposure.

Human volunteers were used to estimate the median detectable concentration of perchloryl fluoride gas. The concentration detected by 50% of the tested personnel was 41 ppm. This value differed significantly from a previously published value of 10 ppm.

The lethal concentration LC_{50} with mice after a 4-h inhalation period was 630 ppm. This relatively high concentration indicated that ClO_3F was not as toxic as elemental fluorine or chlorine trifluoride. In a long-term test where groups of rats were exposed to 200 ppm ClO_3F for 8 h/day, 5 days/week there were no fatalities, but poisoning symptoms were evident from external observation. Similar tests with only 40 ppm with groups of rats and guinea pigs were extended for 3 months, and produced no externally visible poisoning symptoms. The necropsy of the animals after an observation period showed that spleen and lungs were enlarged, and the red blood cell count indicated damage to the platelets. See also [519].

Some of the acute toxicity data for perchloryl fluoride are summarized in Table 46.

Table 46: Acute toxicity lethal concentration data for perchloryl fluoride.

Species	LC_{50} , ppm	LC_{Lo} , ppm	Time	Adjusted 0.5-h LC (CF)	Derived value	References
Rat	—	2000	40 min	2200 ppm (1.1)	220 ppm	[241]
Rat	385	—	4 h	770 ppm (2.0)	77 ppm	[518]
Mouse	630	—	4 h	1260 ppm (2.0)	126 ppm	[518]
Dog	—	451	4 h	902 ppm (2.0)	90 ppm	[520]

Data source: [521]

5.1.3 Chlorine Tetraoxygen Fluoride (also called “Fluorine Perchlorate”)

Chlorine tetraoxygen fluoride, ClO_4F , chlorine tetraoxyfluoride, ClO_4F , and chlorine dioxygen trifluoride ClO_2F_3 [522, 523] are unstable and cannot be used as rocket propellants.

Chlorine tetraoxygen fluoride, fluorine perchlorate, ClO_4F , ClO_3OF , CAS RN [10049-03-3], is colorless as a gas and a liquid and white as a solid. It was found to be stable at room temperature in either Teflon or passivated steel containers and to be the most stable member of the series ClO_3OF , ClO_3OCl , or ClO_3OBr . Although fluorine is usually the most electron-negative part of a molecule, it seems that under certain conditions fluorine can carry a formal positive charge and in those situations names such as fluorine nitrate or fluorine perchlorate may be justified.

5.1.3.1 Preparation of Chlorine Tetraoxygen Fluoride

Chlorine tetraoxygen fluoride, fluorine perchlorate, ClO_4F can be prepared by the reaction of elemental fluorine with 60% perchloric acid in a trickle column packed with glass chips [524]. Oxygen difluoride was observed as a byproduct in this reaction. It was reported that ClO_3OF consistently exploded when frozen. Fluorine perchlorate can also be prepared by reacting an aqueous solution of an alkali metal perchlorate salt with fluorine [525]. Chlorine tetraoxygen fluoride is extremely sensitive to shock

and contact with grease and often exploded before it could be collected for additional study of its properties.

Repeated explosions were encountered at the attempt to determine its melting point, which was eventually found to be near 105.85 K (−167.3 °C). As a precaution, no sample larger than 4 mL has ever been collected. The molecular mass calculated from the gas density (assuming the molecule is not associated in the gas phase) was 120 (theoretical mass is 118.46).

Very pure ClO_3OF could be obtained by the decomposition of NF_4ClO_4 [526]. The ClO_3OF prepared in this manner could be safely manipulated and frozen without explosions [527].

5.1.3.2 Physical Properties of Chlorine Tetraoxygen Fluoride

In view of its explosive nature, it is not surprising that very few papers dealing with ClO_3OF have been published since it was first discovered. The ^{19}F NMR spectrum of ClO_3OF in CFCl_3 and four infrared absorptions of the gas were reported [528]. The same four infrared bands at 1298, 1049, 885, and 666 cm^{-1} have also been observed in a later study in which the heat of hydrolysis was measured for ClO_3OF .

Infrared spectra of gaseous, solid, and matrix-isolated ClO_4F and Raman spectra of liquid ClO_4F were measured and all 12 fundamental vibrations expected for the covalent perchloric structure of symmetry C_s were observed and assigned [529]. A modified valence force field was computed for ClO_3OF by using the observed ^{35}Cl – ^{37}Cl isotope shifts, symmetry relations between the A' and the A'' block, and the off-diagonal symmetry force constants of the closely related FCLO_3 molecule as constraints. Previous assignments for ClO_3OCl , ClO_3OBr , ClO_3OCF_3 , and Cl_2O_7 had to be revised. The ^{19}F NMR spectrum of ClO_3OF was recorded, and thermodynamic properties were computed in the range 0–2000 K. The relative enthalpy of formation, $(\Delta H_T - \Delta H_0)$ of gaseous ClO_4F was $+15.03\text{ kJ/mol} = +3.592\text{ kcal/mol}$. See also [530, 531].

The heat of formation of fluorine perchlorate, ClO_4F , has been determined to be $+157.3 \pm 37\text{ kJ/mol}$ ($+37.6 \pm 9\text{ kcal/mol}$) from the measured value of the heat of hydrolysis [498]. An essentially corroborating value of $155 \pm 63\text{ kJ/mol}$ ($+37 \pm 15\text{ kcal/mol}$) for the heat of formation was obtained from the heat release from the reaction of fluorine perchlorate with hydrogen in a calorimetric bomb. However, experimental limitations contributed to the great uncertainty associated with this value.

5.1.3.3 Chemical Properties of Chlorine Tetraoxygen Fluoride

Under carefully controlled conditions, similar to earlier work with the addition of ClOClO_3 and BrOClO_3 to olefinic double bonds, fluorine perchlorate was found to add to fluorocarbon olefinic double bonds, such as in tetrafluoroethylene [527].

5.1.4 Chlorine Trifluoride Oxide ClF₃O

Chlorine trifluoride oxide, also known as chlorine monoxide trifluoride, oxychlorine trifluoride, ClF₃O, CAS RN [30708-80-6], was independently discovered in 1965 at Rocketdyne and in 1970 at Saclay. If it could be produced in larger quantities, it would make a good high-energy rocket propellant oxidizer, a storable version of FLOX.

5.1.4.1 Preparation of Chlorine Trifluoride Oxide

Chlorine trifluoride oxide has been prepared by either direct fluorination of Cl₂O, NaClO₂ or ClONO₂, or by glow discharge of F₂ in the presence of solid Cl₂O [532]. Chlorine trifluoride oxide can be synthesized by way of several gaseous reactions using UV activation at 213 K (−60 °C). The fluorination of both ClO₂F or ClO₃F, using ClF₅ or F₂ as fluorinating agents, gave excellent yields of ClF₃O [310]. Chlorine trifluoride oxide can be prepared by irradiating with UV at 193–283 K (−80 to +10 °C) a mixture of ClO₂F or ClO₃F with a fluorinating agent, such as ClF₃, ClF₅, ClF, OF₂, or F₂ [533]. In addition, the direct photochemical synthesis of ClF₃O from the elements Cl₂, F₂, and O₂ was successfully achieved. Other systems yielding ClF₃O on UV illumination were ClF₃ + O₂ and ClF₃ + IF₅O. All these processes give mixtures of chlorine fluorides and chlorine oxyfluorides that need to be separated before the pure compound can be analyzed any further. The most convenient and practical reaction system for the photochemical synthesis of ClF₃O is obviously the one starting from the elements Cl₂, F₂, and O₂. An intermediate forming first is ClF₃; thus, one might as well skip the first reaction step and start directly with ClF₃, F₂, and O₂.

New syntheses of ClF₃O were discovered utilizing UV-initiated reactions of FClO₂ and FClO₃ [534]. In the presence of F₂, ClF₃, or ClF₅, FClO₂ gave ClF₃O in high conversions and high yields. The most effective fluorinating agent was ClF₅. The same techniques were not successful in oxidizing ClF₃O to ClF₅O or BrF₅ to BrF₇. There is some evidence that FClO is an intermediate in the synthesis of ClF₃O by UV activation. Corona discharge activation in the systems FClO₂/F₂ did not result in ClF₃O. In the mass spectrometer, a stable mass cracking pattern for ClF₃O was obtained with the most prominent peaks assignable to ClFO⁺ (100%), ClF₂O⁺ (80.60%), Cl⁺ (29.35%), ClF⁺ (21.23%), and ClO⁺ (14.78%). The ¹⁹F NMR spectrum of gaseous ClF₃O revealed two bands at −276ϕ and −317ϕ with respective ratios of 2 and 1. These bands support the proposed C_s symmetry for ClF₃O.

The use of N₂O as an oxygen source for the synthesis of ClF₃O was successful but offered no advantages over oxygen [535].

Experiments showed that some ClF₃O was indeed formed during the photolysis of N₂O/ClF₃, but no significant advantage over the O₂/ClF₃ reactant system was apparent.

The illumination of a mixture of ClF_3 and F_2O with UV light gives a mixture of ClOF_3 and ClF_5 [536]:

5.1.4.2 Physical Properties of Chlorine Trifluoride Oxide

Pure ClF_3O is colorless as a gas or liquid and white in the solid state. It boils at 302 K (+29 °C) and freezes at 231 K (−42 °C). Vapor pressures were measured over the range 250 to 304 K (−23 to +31 °C) and the data were fitted to the equation

$$\log P_V = 8.433 - 1680/T$$

where P_V is the vapor pressure in mm Hg and T is the temperature in kelvin. The latent heat of evaporation is 32.2 kJ/mol (7.7 kcal/mol). The density at 293 K (20 °C) is 1.865 g/cm³, which is similar to the densities of ClF_3 and ClF_5 .

The IR spectra of gaseous, solid, and matrix-isolated ClF_3O and the Raman spectra of gaseous and liquid ClF_3O showed nine fundamental vibrations, consistent with symmetry C_v . The vibrational spectra of ClF_3O agreed well with a trigonal-bipyramidal model with two fluorine atoms at the apexes and one fluorine atom, one oxygen atom, and one localized free electron pair at the remaining corners [81]. Thermodynamic properties were computed for ClF_3O in the range 0–2000 K. The differential enthalpy of formation of gaseous (ideal gas at 1 atm) ClF_3O is $(\Delta H_{298} - \Delta H_0) = 15.6 \text{ kJ/mol} = 3.732 \text{ kcal/mol}$.

5.1.4.3 Molecular Structure of Chlorine Trifluoride Oxide

Until 1982, no structural data had been published for this compound, except for its vibrational and ^{19}F MR spectra, which were in agreement with a pseudo-trigonal-bipyramidal structure of symmetry C_s . In this structure, two fluorines occupy the axial positions and one fluorine, one oxygen, and one sterically active free valence electron pair occupy the equatorial positions. Based on electron diffraction measurements, chlorine trifluoride oxide is a distorted-trigonal-bipyramidal molecule with three different ligands in the equatorial plane: a single bond, a double bond, and a lone valence electron pair [537]. The angles between the axial bonds and the double bond are larger (by about 7°) than the angles between the axial bonds and the single bond or the lone electron pair; i.e., the axial fluorine atoms are bent away from the double bond into the sector between the single bond and the lone electron pair. The observed bond distances ($\text{Cl}=\text{O} = 1.405 \text{ \AA}$, $\text{Cl}-\text{F}_{\text{eq}} = 1.603 \text{ \AA}$, $\text{Cl}-\text{F}_{\text{ax}} = 1.713 \text{ \AA}$) agreed well with previous estimates. The $\angle \text{F}_{\text{eq}}-\text{Cl}-\text{F}_{\text{ax}}$ angle is 87.9° and the $\angle \text{F}_{\text{ax}}-\text{Cl}-\text{F}_{\text{ax}}$ angle is 170.5°.

Chlorine trifluoride oxide ClF_3O was crystallized from the melt at 231 K (−42 °C) and the crystals were analyzed by XRD to give the cell dimensions as $a = 982.6(2) \text{ pm}$, $b = 1229.5(2) \text{ pm}$, $c = 490.1(1) \text{ pm}$, $\beta = 90.338(4)^\circ$, space group $C_{2/m}$ [538]. The asymmetric unit cell contains two crystallographically non-equivalent, pseudo-trigonal bipyramidal molecules in which two fluorine atoms occupy the axial and one fluorine atom, the oxygen atom and one sterically active, free valence electron pair of chlorine oc-

cupy the three equatorial positions. The structure, vibrational frequencies, isotopic shifts and force field of ClF_3O were calculated by MO methods and were in very good agreement with the observed values.

5.1.4.4 Chemical Properties of Chlorine Trifluoride Oxide

Chlorine trifluoride oxide resembles most chlorine fluorides in its corrosive and oxidizing properties. However, it appears to be somewhat more corrosive than either ClF_3 or ClF_5 .

Reactions of Chlorine Trifluoride Oxide

Chlorine trifluoride oxide, ClF_3O , is a strong oxidizer and ignites hypergolically with many fuels. When ClF_3O was heated to 553 K (280 °C) in a Monel bomblet for 16 h, 70% of the ClF_3O was decomposed to ClF_3 and oxygen.

The reaction of ClF_3O with elemental chlorine does not start at room temperature, but if heated with Cl_2 to 473 K (200 °C) for 16 h it converts to ClF . At ambient temperature, chlorine trifluoride oxide and N_2F_4 do not react. An equimolar mixture of the two was heated in a stainless steel cylinder at 403 K (130 °C) for 15 h before separating the products by fractional condensation. No unreacted N_2F_4 was recovered, the main product was NF_3 . The reaction of ClF_3O with PtF_6 formed a yellow solid identified as $[\text{ClF}_2\text{O}^+][\text{PtF}_6^-]$ and released F_2 gas [539].

Chlorine trifluoride oxide readily hydrolyzes with water. The reaction of chlorine trifluoride oxide with water was studied using DFT [540]. Results showed that the energy barriers of the reaction of chlorine trifluoride oxide and water are very low, and an excess of water produces HF , HClO_2 , and HClO_4 ; however, insufficient water produces HF and ClFO_2 .

Salts Derived from Chlorine Trifluoride Oxide

Chlorine trifluoride oxide, ClF_3O , is amphoteric and forms adducts and salts with Lewis acids as well as Lewis bases. The thermal stability of these adducts decreases in the order: $\text{ClF}_3\text{O}\cdot\text{SbF}_5 > \text{ClF}_3\text{O}\cdot\text{AsF}_5 > \text{ClF}_3\text{O}\cdot\text{BF}_3 > (\text{ClF}_3\text{O})_2\cdot\text{SiF}_4$ [541].

The infrared and Raman spectra of $\text{Cs}^+\text{ClF}_4\text{O}^-$ and $\text{Rb}^+\text{ClF}_4\text{O}^-$ were consistent with a C_{4v} structure analogous to that of XeF_4O and ClF_5 [542]. The bonding in ClF_4O^- is best described by a mainly covalent $\text{Cl}=\text{O}$ double bond and two semi-ionic, three-center, four-electron p-p σ $\text{Cl}-\text{F}$ bond pairs.

The vibrational spectra have been recorded for the solid 1:1 Lewis acid adducts with chlorine trifluoride oxide, $\text{ClF}_3\text{O}\cdot\text{BF}_3$, $\text{ClF}_3\text{O}\cdot\text{AsF}_5$, and $\text{ClF}_3\text{O}\cdot\text{SbF}_5$ and for $\text{ClF}_3\text{O}\cdot\text{BF}_3$ in HF solution [543]. These spectra were entirely consistent with the ionic structures, $[\text{ClF}_2\text{O}^+][\text{BF}_4^-]$, $[\text{ClF}_2\text{O}^+][\text{AsF}_6^-]$, and $[\text{ClF}_2\text{O}^+][\text{SbF}_6^-]$ respectively. The structure of ClF_2O^+ can be derived from a tetrahedron with the chlorine atom located at the center and with two fluorine atoms, one oxygen atom, and one free electron pair at the four corners.

5.1.5 Dioxygen Chlorine Trifluoride

Dioxygen difluoride, O_2F_2 , reacts with Cl_2 , ClF , or HCl and under certain conditions forms a deep violet addition product, called dioxygen chlorine trifluoride or chlorine trifluoride dioxide (O_2ClF_3)_n [544–546]. If the reaction between O_2F_2 and ClF is carried out under mild conditions, from just above the melting point of ClF (119 K) up to 130 K, an intense violet-colored intermediate compound of the elementary composition (O_2ClF_3)_n (referred to simply as O_2ClF_3) is formed:

Its color and hue are very similar to those of the organic dye methyl violet. Dioxygen chlorine trifluoride O_2ClF_3 is a solid, thermally stable up to 195 K. At this temperature it can be kept for over a year. It has a vapor pressure of less than 12 microns at 158 K. At this pressure and temperature it sublimates and dissociates into its components, which can be collected on a liquid nitrogen finger (77 K). If the cold finger is warmed up to 119–140 K, the violet compound forms again. The compound is insoluble in LOX at 90 K, in liquid ClO_3F at 140 K, and in liquid NF_3 at 160 K. It is soluble in ClF at 125 K, O_2F_2 at 140 K, and ClF_3 at 190 K. It is readily soluble in anhydrous HF at 190 K, forming a deep violet solution [523]. In the same report, it was also reported that dioxygen chlorine trifluoride can be synthesized from chlorine trifluoride and oxygen under pressure and UV illumination. The color of the ClF_3 solution increased appreciably with time. Dioxygen chlorine trifluoride is a strong oxidizer similar to O_2F_2 but not as powerful. When gaseous NH_3 was admitted to a reaction vessel containing O_2ClF_3 at 90 K, a reaction took place with a flash, forming white solids and some nitrogen-containing gases, whereas the violet color disappeared. Dioxygen chlorine trifluoride did not react with hydrogen or methane at 140 K, but did ignite with ethane or ethylene.

Chlorine trifluoride dioxide was prepared from FNO_2 and $ClO_2F_2PtF_6$, the latter being synthesized from $FClO_3$ and PtF_6 [547, 548]. The NMR spectrum suggested a trigonal–bipyramidal structure of symmetry C_{2v} . Chlorine trifluoride dioxide formed stable adducts with BF_3 and AsF_6 but not with FNO , FNO_2 , or CsF . Pure ClF_3O_2 is colorless as a gas or liquid and white in the solid state. It melts at 191.9 K (–81.2°C). Vapor pressure was measured over the range 177 to 241 K (–96 to –32°C) and the data were fitted by the method of least squares to the equation

$$\log P = 7.719 - 1217.2/T$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin. The extrapolated boiling point is 251.57 K (–21.58°C). The latent heat of vaporization of ClF_3O_2 is 23.3 kJ/mol (5.57 kcal/mol). It reacts explosively with organic materials and care must be taken to avoid such combinations.

The IR spectra of gaseous, solid and matrix-isolated ClF_3O_2 and the Raman spectra of gaseous and liquid ClF_3O_2 were measured and 12 fundamental vibrations were observed, consistent with a structure of symmetry C_{2v} . A modified valence force field and thermodynamic properties were computed for ClF_3O_2 [549]. The question

is whether the two oxygen atoms are in axial or in equatorial positions. Proof for a pseudo-trigonal-bipyramidal structure of symmetry C_{2v} was obtained from its ^{19}F NMR spectrum, which showed an AB2 pattern with strong evidence for the two equivalent fluorine atoms occupying the apical positions. The relatively low boiling point (251.6 K = -21.5°C) and Trouton constant (22.13) of ClF_3O_2 imply little association in the liquid phase. The differential enthalpy of formation of gaseous (ideal gas at 1 atm) ClF_3O_2 is $(\Delta H_{298} - \Delta H_0) = 16.9 \text{ kJ/mol} = 4.049 \text{ kcal/mol}$.

The difluoroperchloryl cation, ClO_2F_2^+ , was prepared in the form of its PtF_6^- salt by reacting FClO_2 with PtF_6 in a sapphire reactor at 209 K = 25°C [550]. The following competing reactions were observed:

Cesium difluorochlorate(V), $\text{Cs}^+\text{ClO}_2\text{F}_2^-$, can be prepared from cesium fluoride and chloryl fluoride [551]. The IR and the Raman spectra of $\text{Cs}^+\text{ClO}_2\text{F}_2^-$ were consistent with a ClO_2F_2^- anion of symmetry C_{2v} . The structure can be derived from a trigonal bipyramid, where the two F atoms occupy the axial and the two O atoms and the lone electron occupy the equatorial positions.

5.1.6 Chlorine Pentafluoride Oxide

Chlorine(VII) pentafluoride oxide, also named chlorine(VII) oxygen pentafluoride, chlorine oxopentafluoride, OClF_5 , has not yet been synthesized, and attempts to make it were unsuccessful. Several attempts to prepare chlorine oxygen pentafluoride, OClF_5 have been unsuccessful.

5.2 Bromine Oxygen Fluorides

5.2.1 Bromyl Fluoride

Bromyl fluoride, bromine dioxygen fluoride, BrO_2F , CAS RN [22585-64-4], is not a very powerful oxidizer and will most likely never be used as a rocket propellant. It is included here only for comparison with some of the chlorine oxygen fluorides that contain chlorine instead of bromine [552].

5.2.2 Bromine Trifluoride Oxide

Bromine trifluoride oxide, bromine oxyfluoride, BrF_3O , CAS RN [61519-37-7], will most likely never be used as a rocket propellant. It is of interest mostly as an analog to the more energetic chlorine trifluoride oxide, which would make a good rocket propellant if it became available in larger quantities and if there was no concern about the toxicity of either the propellant and/or the exhaust products.

Bromine trifluoride oxide was prepared from KBrF_4O and O_2AsF_6 by a displacement reaction in BrF_5 . The starting materials KBrF_4O and O_2AsF_6 had to be prepared in the laboratory. On the basis of incomplete vibrational spectra, IR spectra of gaseous, solid, and matrix-isolated BrF_3O and the Raman spectra of solid and liquid BrF_3O and of its HF and FClO_3 solutions, a structure of symmetry C_s was proposed for BrF_3O [553]. A detailed investigation and analysis of the vibrational and ^{19}F NMR spectra confirmed the previously proposed structure of a pseudo-trigonal-bipyramidal structure of symmetry C_s with two fluorine atoms at the apexes and one fluorine, one oxygen, and one localized free electron pair at the remaining corners. The bond lengths and angles were $D(\text{Br}-\text{O}) = 1.56 \text{ \AA}$, $R(\text{Br}-\text{F}') = 1.72 \text{ \AA}$, $r(\text{Br}-\text{F}) = 1.81 \text{ \AA}$, $\angle\alpha(\text{O}-\text{Br}-\text{F}') = 120^\circ$, and $\angle\beta(\text{O}-\text{Br}-\text{F}) = \angle(\text{F}'-\text{Br}-\text{F}) = 90^\circ$. The differential enthalpy of formation ($\Delta H_{298} - \Delta H_0$) of the gas at 298 K is 16.9 kJ/mol (4.050 kcal/mol). See Ellern et al. [538].

A potential high-energy oxidizer is dioxygen bromine pentafluoride, O_2BrF_5 , prepared by reaction of dioxygen difluoride with bromine trifluoride [554]:

Similar compounds are available with iodine instead of bromine as the central atom, but there does not seem to be any practical use for such oxidizers and they are only of academic interest.

5.3 Iodine Oxygen Fluorides

Iodine oxygen fluorides are only of theoretical interest, in particular when the iodine atom is oxidized to its +7 state of oxidation. They are not likely to be used as rocket propellants, but can serve as intermediates or templates in the synthesis of more powerful oxidizers. A new compound of iodine(VII), IOF_5 , was prepared in pure state in bulk quantities by the reaction of IF_7 with H_2O or SiO_2 , followed by the removal of unreacted IF_7 from the resulting IOF_5 mixture with SbF_5 . IOF_5 was characterized by its IR and ^{19}F NMR spectra [555].

6 Other Halogen Perchlorates

Halogen perchlorates are no fluorine compounds, but closely related to the chlorine oxygen fluorides. Halogen perchlorates are shock sensitive and should be handled with proper safety precautions. Chlorine perchlorate, ClOClO_3 , was synthesized from the action of chlorine fluorosulfate on several perchlorate salts [535]. The low-temperature IR spectrum of solid ClOClO_3 was recorded by condensing the sample on the cold ($77 \text{ K} = -196^\circ\text{C}$) internal AgCl window of a conventional low-temperature cell [556]. From the vibrational spectra the thermodynamic properties

could be calculated. The differential enthalpy of formation of gaseous (ideal gas at 1 atm) ClOClO_3 is $(\Delta H_{298} - \Delta H_0) = +17.4 \text{ kJ/mol} = +4.161 \text{ kcal/mol}$. Similar data were obtained for bromine perchlorate. Bromine perchlorate can be prepared by a method using bromine(I) fluorosulfate [557]

The oxidation of elemental bromine with chlorine perchlorate also forms bromine perchlorate

Hydrazinium Salt Oxidizers

Hydrazinium salts have the advantage that they do not introduce condensable oxide-forming cations such as sodium or potassium. They share this advantage with ammonium cations, but hydrazinium cations are more energetic than ammonium cations. On the other hand, in both ammonium and hydrazinium salts with oxidizing anions, some of the oxidizing power of the anion is consumed in burning the hydrogen that is carried in with the hydronitrogen cation.

Although ammonium and hydrazinium nitrates and perchlorates can burn by themselves if the decomposition is accelerated by burning rate additives, the mono-solid burning does not offer any advantages over formulations that contain organic binders. The mono-solid burning is done mostly for academic reasons to characterize the ammonium or hydrazinium salt before mixing it in with other ingredients, mainly binders. **Caution:** The strand-burning decomposition of pure hydrazinium salts can spontaneously transition into a detonation.

Even relatively inert salts such as hydrazinium sulfate can explode when heated in concentrated solutions with an open flame to near dryness. During a student preparation of hydrazinium sulfate, using a standard preparative method, the liquid reaction mixture detonated violently [1]. The containing evaporating dish was shattered, and the asbestos gauze was driven down through the opening of the supporting tripod.

This chapter also contains a section on hydrazinium azide (HA), which, although not an oxidizer, is an energetic additive and one of the marginally stable compounds with the highest possible nitrogen content (see Section 5).

1 Hydrazinium(1+) Nitrate

The chemical name “hydrazinium nitrate” is not unambiguous, because there are two hydrazinium nitrates, depending on the degree of protonization of the hydrazine molecule: Hydrazinium ions can exist as mono-protonated hydrazinium(1+) ions and di-protonated hydrazinium(2+) ions. Hydrazinium(2+) salts are formed only with very strong acids, such as perchloric acid. If the (1+) or (2+) designator is missing in a report referring to hydrazinium nitrate, it is safe to assume that the author is writing about the more common hydrazinium(1+) nitrate. Foreign language publications often call this compound “*hydrazonium nitrate*”, but this is not the IUPAC-recommended nomenclature. The term “hydrazine nitrate” is often found in the literature, but is not correct. We would not call ammonium nitrate (AN) ammonia nitrate, would we?

The nomenclature question is if the hydrazinium(2+) salts should be named dianion such as hydrazinium(2+) dinitrate or simply hydrazinium(2+) nitrate. It appears that the (2+) designator should clearly indicate that there must be two nitrate anions in the neutral salt as long as it does not carry any electrical charges.

Hydrazinium nitrate is often abbreviated here as HN. This abbreviation is not to be confused with the diatomic imidogen radical NH. A very detailed summary of the properties of hydrazinium(1+) nitrate and hydrazinium(2+) dinitrate was already published in the author's earlier books on hydrazine: The first edition [2], pages 120 through 272, and the significantly expanded second edition [3], pages 220 through 375, contain information on all hydrazinium salts. Additional information on hydrazinium nitrate is contained in the book by Patil and Rattan [4], pages 37 through 46. The main emphasis in the current chapter is on publications that have appeared in the interim or that were not already included in the two earlier books. For literature searches in the Chemical Abstracts, SciFinder or similar databases it is very useful to have the CAS Registry numbers, which identify the two hydrazinium nitrates with unique numbers:

Hydrazinium(1+) nitrate CAS RN 37836-27-4

Hydrazinium(2+) nitrate CAS RN 13464-98-7

1.1 Production of Hydrazinium(1+) Nitrate

Producing hydrazinium(1+) nitrate by mixing aqueous solutions of hydrazine hydrate and nitric acid would be a simple acid-base neutralization reaction, as long as the reactants are sufficiently diluted and the evolved heat is effectively carried away. What happens if the dilution is not sufficient is called hypergolic ignition and more of this reaction will be discussed in a future volume in this Encyclopedia, *Encyclopedia of Hypergolic Bipropellant Combinations*.

It is also possible to produce HN in non-aqueous media, starting with hydrazinium carbazate. As nitric acid is a stronger acid than carbonic acid, it replaces carbonic acid, carbon dioxide escapes and HN remains in suspension as a salt that is easily dried [5]. In one example, 50 g of hydrazinium carbazate was suspended in chlorofluoroethylene, and treated with 34 g of a fine jet of cold HNO_3 ($\rho = 1.5 \text{ g/cm}^3$) with efficient cooling until a pH of 5.2–5.4 was attained and until the evolution of gas ceased, giving an almost pure powdered HN. The precipitated HN was filtered off with suction and washed with 250 mL MeOH. The yield was 48 g HN.

A similar method avoids or at least minimizes the use of water by working in methylene chloride suspension [6]. For example, 5 g of hydrazine hydrate were mixed with 25 mL CH_2Cl_2 and stirred vigorously. Then, 55 mL of 10.9 vol.-% HNO_3 , cooled to 293–298 K (20–25 °C) was added until a mildly acidic pH was obtained. The precipitate was filtered and 6.2 g of 97% pure HN was obtained. See also [7, 8].

1.2 Physical Properties of Hydrazinium(1+) Nitrate

The physical properties of hydrazinium nitrate are summarized in Table 1.

Table 1: Physical properties of hydrazinium nitrate.

Property	SI Units	Other units	References
Molecular mass	95.058 g/mol	10.5197 mol/kg	
Melting point, α -HN	343.6 K	70.5 °C	[9]
Melting point, β -HN	335.6 K	62.5 °C	[9]
Density at 298 K	1.661 g/cm ³		[9]
Enthalpy of formation	-246.2 $\pm$ 0.96 kJ/mol	-58.86 $\pm$ 0.23 kcal/mol	[10]

1.2.1 Melting Point and Phase Diagrams of Hydrazinium(1+) Nitrate

Hydrazinium(1+) nitrate exists in two crystalline forms, the α and the β modification. The β form is unstable, and only a few properties other than its melting point and the refractive index are known. The β modification of HN melts at a lower temperature than the α modification. α -Hydrazinium(1+) nitrate melts at 343.6 K [9, 11], and the β modification melts 8° lower at 335.6 K. Melting points reported 100 years ago differ only by fractional degrees [12]. The solidifying melt kept at a temperature between 335 and 343 K (62 and 70 °C) only slowly converts to the α modification. Table 2 contains a summary of melting points for hydrazinium nitrates.

Table 2: Melting points of hydrazinium nitrates.

Compound	Melting point		Author	References
	K	°C		
N ₂ H ₅ NO ₂	315	42	Miron and Perlee	[13]
β -N ₂ H ₅ NO ₃	335	62	Perlee et al.	[14]

N ₂ H ₅ (NO ₃) ₂	376	103	Miron and Perlee	[13]

1.2.1.1 Melting Points of Binary Hydrazinium(1+) Nitrate Systems

On occasions, it may be advantageous to mix HN with other nitrate salts in order to reduce its sensitivity. Various alkali metal nitrates have been mixed with HN to determine low-melting compositions and to find out if they form eutectic melts. The eutectic compositions and melting points of mixtures of five alkali metal nitrates or ammonium nitrate (AN) with hydrazinium nitrate are listed in Table 3.

Table 3: Melting points of hydrazinium nitrate salt binary eutectics.

Additive	$\text{N}_2\text{H}_5\text{NO}_3$	Melting point	
	Mass-%	$^{\circ}\text{C}$	K
Ammonium nitrate	68	43	316
Cesium nitrate	64	43	316
Lithium nitrate	85	25	298
Potassium nitrate	95	54	327
Rubidium nitrate	78	36	309
Sodium nitrate	95	47	320

Data source: [20]

No well-defined compounds or double salts could be identified in these inorganic binary systems. The literature contains melting point diagrams for many binary compositions containing between 100 and 30% hydrazinium nitrate. The data in Table 3 were derived from the melting point minima of these curves.

A study of the phase diagrams of the $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3$ and $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{Cl}$ systems revealed formation of the complexes $\text{N}_2\text{H}_4 \cdot \text{N}_2\text{H}_5\text{X}$ ($\text{X} = \text{NO}_3$ or Cl), which dissociate at temperatures close to their melting points (276 and 237 K respectively; +3 and -36°C respectively) [21]. Crystallization of metastable $\beta\text{-N}_2\text{H}_5\text{NO}_3$ depressed the freezing point of the system by $8\text{--}10^{\circ}$. When kept at temperatures lower than the melting points of the eutectics of the system, a phase transition from β - to $\alpha\text{-N}_2\text{H}_5\text{NO}_3$ took place.

Melting points of a eutectic mixture of hydrazinium(1+) nitrate and nitroguanidine (NQ) and fusion enthalpy of the pure components and the eutectic were determined using differential scanning calorimetry (DSC) [22]. The structure of the HN/NQ eutectic was characterized by infrared (IR), X-ray diffraction (XRD), and scanning electron microscopy (SEM). Thermodynamic functions such as excess Gibb's energy, excess enthalpy, and excess entropy of the HN/NQ eutectic were calculated using activity coefficient data. The intermolecular interactions of different molar ratios of the HN/NQ eutectic were determined by density functional theory methods. IR spectroscopic and XRD studies confirmed that there is some interaction between the components during the formation of the eutectic mixture. In particular, the microstructure of the eutectic mixture at a molar ratio of 3:2 was more uniform than others. Similar eutectics were formed with methylnitroguanidine and hydrazinium(1+) nitrate [23].

A study of eutectic and peritectic points in the binary systems HN/nitroguanidine (HN/NQ) and HN/methylnitroguanidine (HN/MeNQ) detected indications of double salt formation with a well-defined stoichiometric ratio. The HN/NQ binary system showed the presence of a new substance, which is probably a HN/NQ co-crystal. No new substance was detected in the MeNQ/HN binary system [24]. The HN/NQ system had two eutectics, one at an NQ mol fraction of 0.226 melting at 322 K (49°C) and another at a mol fraction of 0.95 melting at 416 K (143°C). In between was a peritectic

melting at 500 K (227 °C) with a composition of three mols of NQ per mol of HN. The HN/MeNQ had only one eutectic at a MeNQ mol fraction of 0.307 melting at 341.7 (68.6 °C).

1.2.1.2 Freezing Points of Hydrazinium Nitrate Solutions

The binary system hydrazine/hydrazinium nitrate has been thoroughly investigated. Within a few years of each other, two different organizations, JPL and NOTS, produced two sets of data that agreed quite well with each other. Deviations do not exceed a few degrees at worst, and most of the time the two curves were within 1 °C of each other. The data of Elverum and Cole [25] were used in drawing the phase diagram in Figure 1. The phase diagram indicates the formation of a hydrazinium nitrate hydrazinate $\text{N}_2\text{H}_5\text{NO}_3 \bullet \text{N}_2\text{H}_4$ with a melting point of 274.8 K. There are two eutectics, one located on either side of the 1:1 compound, the lower-melting eutectic containing 45% HN and melting at 223.3 K (−57.6 °F). See also [21].

The melting points in the binary system HN/H₂O have to be known for successful crystallization of HN during the careful preparation of this salt in aqueous solutions, and also to prevent the inadvertent precipitation of the shock-sensitive HN from aqueous HN solutions during storage. The melting point of the hydrazinium nitrate/

Figure 1: Freezing point of hydrazinium nitrate/hydrazine solutions. (From [2].)

water system was investigated repeatedly during the 1950s, with generally good agreement [25, 26]. The graph in Figure 2 is a combination of data from different sources. The system has a simple eutectic containing 37.5 mass-% HN and melting at 263.9 K (-9.2°C). Melting point data reported by other investigators [27, 28] were less accurate.

Figure 2: Melting point as a function of composition for the hydrazinium nitrate/water system. (Reproduced and modified from [3].)

1.2.1.3 Melting Points of Ternary Hydrazinium(1+) Nitrate Systems

Phase diagrams of ternary systems involving ammonium nitrate, hydrazinium(1+) nitrate, and any one of the following five nitrates could be calculated and triangular charts drawn using the Krupkowski equation or Kleppa-Hersh equation: lithium nitrate, sodium nitrate, potassium nitrate, hydroxylammonium nitrate (HAN), and hydrazinium(2+) dinitrate [29]. The data are summarized in Table 4.

The lowest-melting eutectic in the latter system was predicted to melt at only 300 K (27°C), which would qualify it as an ionic liquid. Even lower-melting systems are formed with small amounts of water contamination. Many of these low-melting eutectics are of practical interest in emulsion explosives or emulsion propellants. This is an interesting mathematical analytical technique to obtain phase diagrams when experimental measurements are not yet available.

Ternary hydrazinium nitrate systems have been developed both as solid and liquid oxidizers and as monopropellants. One of the most thoroughly investigated

Table 4: Composition, melting points, and densities of calculated lowest melting eutectics of hydrazinium(1+) nitrate/ammonium nitrate/other nitrate ternary systems.

Ingredient XN	Composition, mass-% AN/HN/XN	Melting point		Density g/cm ³
		°C	K	
Lithium nitrate	40/42/18	28	301	1.776
Sodium nitrate	36/53/11	39	312	1.728
Potassium nitrate	27/72/1	53	326	1.667
Hydroxylammonium nitrate	22/36/42	<27	<300	—
Hydrazinium(2+) dinitrate	30/34/36	27	300	1.664

AN = ammonium nitrate, HN = hydrazinium nitrate, XN = other nitrate

Data source: [29]

ternary systems involving free hydrazine (or hydrazine hydrate), one other liquid component, and one salt is the hydrazine/water/hydrazinium nitrate system. The $\text{N}_2\text{H}_4/\text{H}_2\text{O}/\text{N}_2\text{H}_5\text{NO}_3$ system is separated into two regions by the boundary of detonability, as described in Section 1.6.3. Accordingly, it offers an opportunity to formulate a wide range of propellants and explosives, depending on the choice of composition and the intended application. Next to performance as a propellant or explosive, melting point is the most important selection criterion to meet environmental constraints in different climates. A detailed knowledge of the melting points, eutectic points, and eutectic valleys in the ternary system $\text{N}_2\text{H}_4/\text{H}_2\text{O}/\text{N}_2\text{H}_5\text{NO}_3$ enables one to select propellants for maximum I_{sp} or lowest exhaust gas temperature within certain freezing point boundaries. Military and deep space applications frequently require freezing points below that of pure hydrazine and the addition of hydrazinium nitrate is one way to not only lower the freezing point but also to increase performance.

Melting point data of 32 different $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3/\text{H}_2\text{O}$ mixtures were not quite sufficient for construction of a complete ternary diagram with melting point isotherms and did not yet identify the regions of practical interest, such as the boundary of the 219 K (−65 °F) regime considered essential for low-temperature applications of such mixtures [30]. Initial interest in these mixtures arose because of their possible application as liquid gun propellants, but they have never found actual applications as such. Another partial ternary diagram of the $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3/\text{H}_2\text{O}$ system between 50 and 100% N_2H_4 (remainder varying percentages HN and H_2O) covered only the hydrazine-rich side of the triangle (in addition to the two sides of the triangle that represent binary mixtures reported earlier) [25]. Finally, a more complete thermal analysis of the entire ternary system $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3/\text{H}_2\text{O}$ was carried out [26]. These more complete freezing point data are presented in the ternary freezing point diagram (Figure 3).

Mixtures of hydrazine/methylhydrazine (MMH)/HN and also hydrazine/unsymmetrical dimethylhydrazine (UDMH)/HN have been thoroughly investigated. A mixture with a nominal composition of 23.3% hydrazine, 45.3% MMH, and 31.4% HN freezes at 219.2 K (−65 °F) and has subsequently been named Mixed Hydrazine

Figure 3: Freezing point isotherms of the hydrazine/hydrazinium nitrate/water system. (Based on data from [26], as modified by [2]).

Fuel-1 (MHF-1). These ternary hydrazine blends will be discussed in *Encyclopedia of Monopropellants*, which describes their use as monopropellants.

Another series of monopropellant blends was made from hydrazinium nitrate, hydroxylamine, and water and the code name was MHF-9 [31] (see *Encyclopedia of Monopropellants*).

Liquid HN-based oxidizers contain a solvent and one additional dissolved oxidizer to achieve low freezing points and high densities. Ternary systems AN/HN/H₂O are already described in *Encyclopedia of Oxidizers*, in the chapter “Nitrate Oxidizers,” and the ternary system hydroxylammonium nitrate (HAN)/HN/H₂O is described in *Encyclopedia of Oxidizers*, in the chapter “Hydroxylammonium Salts.” Another variation on this family of dissolved nitrate oxidizers is a solution of HN in H₂O₂/H₂O mixtures, called “PERSOL-2” [32]. The freezing point diagram of the HN/H₂O₂/H₂O system is illustrated in Figure 4. It is known that hydrogen peroxide and free hydrazine or hydrazine hydrate react instantly in a hypergolic manner. The hydrazine molecule appears to be stabilized against such an attack by protonizing and forming the

Figure 4: Freezing point diagram of hydrazinium nitrate/H₂O₂/H₂O system. (Reproduced and modified from [32].)

hydrazinium(1+) ion. When looking at PERSOL-2 type oxidizers, there is some concern that the strong oxidizer H₂O₂ might attack the fuel cation N₂H₅⁺, leading to hydrogen azide as an unwanted byproduct of the reaction. The solution must be examined for the presence of azide soon after it has been made.

Ternary and quaternary mixtures of HN with other inorganic nitrates, predominantly ammonium nitrate and sodium nitrate, also have very low melting points [33–35].

1.2.2 Solubility of Hydrazinium(1+) Nitrate in Water

The solubility of hydrazinium(1+) nitrate in water is summarized in Table 5.

Table 5: Solubility of hydrazinium(1+) nitrate in water.

Temperature, K	Solubility, g/100 g Solution	Temperature, K	Solubility, g/100 g Solution
283	63.63	288	68.47
293	72.70	298	76.61
303	80 ^a		
303	80.09	308	83.06

1.2.3 Density of Hydrazinium(1+) Nitrate

Density data for crystalline HN are summarized in Table 6.

Table 6: Density of hydrazinium(1+) nitrate.

Temperature, K	Density, g/cm ³	Method	Source	References
—	1.661	—	James, Miron, and Perlee	[9]
	1.688	XRD	Xia, Y.-X., et al.	[37]
298	1.665	Flotation in non-solvents	Robinson and McCrone	[11]
298	1.661	XRD	Robinson and McCrone	[11]
298	1.726	XRD	Grigoriev et al.	[38]

1.2.3.1 Density of Binary Hydrazinium Nitrate Solutions

The temperature dependence of the density of aqueous solutions of hydrazinium nitrate with 0–65% HN is illustrated in Figure 5.

Figure 5: Density of hydrazinium nitrate/water solutions at various hydrazinium nitrate concentrations as a function of temperature. (Reproduced and modified from [3].)

The temperature dependence of the density of solutions of hydrazinium nitrate in hydrazine with 0–75% HN is illustrated in Figure 6.

Figure 6: Density of hydrazinium nitrate/hydrazine solutions at various hydrazinium nitrate concentrations as a function of temperature. (Reproduced and modified from [9].)

Other investigations at only one constant temperature (297 K) had shown that the density of HN/water solutions between 0 and 75 mass-% (saturated solution) increased linearly from 1.0 to 1.37 g/cm³ [39] (Figure 7).

1.2.3.2 Density of Ternary Hydrazinium Nitrate Solutions

In the ternary system hydrazine/water/hydrazinium nitrate, the density changes monotonously between the three ingredients (Figure 8).

Figure 7: Density and molarity of aqueous hydrazinium nitrate solutions. (Based on data from [39])

Figure 8: Density of hydrazine/hydrazinium nitrate/water ternary mixtures. (Reproduced and modified from [3].)

1.2.4 Velocity of Sound in Ternary Hydrazinium Nitrate Mixtures

Solutions of hydrazinium nitrate in hydrazine and hydrazine-water mixtures have been tested as rocket propellants and consequently the velocity of sound in several of such solutions has been measured. The velocity of sound is closely related to detonation velocities of liquid explosives. Therefore, the velocity of sound in hydrazine/hydrazinium nitrate/water ternary mixtures was measured and compared with detonation velocity data (*Encyclopedia of Liquid Fuels*, chapter “Hydrazine”) [40]. The velocity of sound can also be used to calculate the compressibility of HN solutions.

1.2.5 Viscosity of Hydrazinium Nitrate Solutions

1.2.5.1 Viscosity of Solutions of Hydrazinium Nitrate in Hydrazine

Comparison of kinematic viscosities of hydrazinium nitrate/hydrazine solutions measured by different investigators in Figure 9 shows that the viscosity of hydrazine increases by one order of magnitude by the addition of 70% HN. Viscosity decreases with temperature as expected.

Figure 9: Kinematic viscosity of hydrazinium nitrate solutions in hydrazine at various hydrazinium nitrate concentrations as a function of temperature. (Reproduced and modified from [3].)

Additional data on viscosity and surface tension of HN solutions in hydrazine are available in the literature [2, 3, 41, 42].

1.2.5.2 Viscosity of Solutions of Hydrazinium Nitrate in Water

Viscosity of most solutions decreases with temperature as expected. A similar trend can be observed for solutions of HN in water, but the relative increase from pure water is not as distinct as with hydrazine as a solvent (Figure 10).

Figure 10: Kinematic viscosity of hydrazinium nitrate/water system at various hydrazinium nitrate concentrations as a function of temperature. (Reproduced and modified from [3].)

Solutions of hydrazinium nitrate in water are of practical interest because they are used in combination with HAN in the reprocessing of nuclear reactor fuel rods.

Somewhat different data for 50, 65, and 76.9% HN solutions in H₂O can be found in Christos et al. [39]. The kinematic viscosity of the most concentrated solution tested (76.9% HN) dropped from 3.2 cSt at 298 K to 1.5 cSt at 327 K. Other authors reported that the kinematic viscosity of HN solutions with 10–72% HN at 293 K increased from 1.0 to 10.5 cSt with increasing HN content [28].

In studying the effect of ion association on viscosity and electrical conductivity, only a few salts are sufficiently soluble in water to study the entire range from 0 to 100 mol-% salt. Hydrazinium salts are sufficiently soluble in water to perform such studies. The dynamic viscosity of HN solutions in water at 298 K increased from 8.95 to 44.37 mPs if the concentration was increased from 0.23 to 38.7 mol-% HN [43]. At 348 K, which is above the melting point of HN, the viscosities could be measured over

the entire range from 2.1 to 100 mol-% HN. In this case, viscosities ranged from 4 to 115 mPs. In combination with simultaneous measurements of electrical conductivity, the conductance-viscosity product, which passes through a minimum at 15 to 20 mol-% salt, was taken as an indication of the dissociation of the salt and beginning association of the ions at higher concentrations.

1.2.5.3 Viscosity of Solutions of Hydrazinium Nitrate in Hydrazine-Water Mixtures

Ternary systems of HN dissolved in hydrazine-water mixtures have been tested as low-freezing monopropellants (see *Encyclopedia of Monopropellants*). Limited viscosity data are listed in Table 7.

Table 7: Viscosity of solutions of hydrazinium nitrate in hydrazine/water mixtures.

HN, mass-%	Water, mass-%	Hydrazine, mass-%	Viscosity, cPs	Viscosity, cSt	at Temp. K
10	27	63	1.984	1.864	298
10	27	63	8.21	7.5	253
10	27	63	112	99.8	219

Data source: [44]

1.2.6 Surface Tension of Solutions of Hydrazinium Nitrate in Hydrazine

The surface tension of hydrazine/HN solutions was measured using a bubble method [45]. The surface tension increased almost linearly with the hydrazinium nitrate mol fraction, except for a narrow range at low concentrations and low temperatures, where the surface tension passed through a shallow minimum. Attempts to calculate the viscosity of 24% HN solution from the parachor were not very accurate. Apparently, the assumptions for incremental addition of parachors are not valid for concentrated, strongly ionized solutions. The surface tension of solutions of HN in hydrazine (Figure 11) or water is a linear function of the temperature and the HN concentration [13].

Mathematical analysis of these data by James et al. [9] showed that the surface tension can be adequately described by the expression

$$\gamma = \gamma_0 + (K_1 C - K_2)(T - T_0)$$

where γ_0 is the surface tension of the solvent in dyn/cm ($T_0 = K$), γ is the surface tension of the solution in dyn/cm ($T = K$), C is the HN concentration (mol-%), and K_1 and K_2 are regression coefficients. For HN-hydrazine solutions, the following data apply: $\gamma_0 = 93.82$, $T_0 = 213.58$, $K_1 = 0.302$, and $K_2 = 0.243$. For aqueous solutions of HN, the following coefficients should be used: $\gamma_0 = 92.69$, $T_0 = 229.45$, $K_1 = 0.220$, and $K_2 = 0.248$. For additional data at constant temperature, compare also Bachmaier and Jimenez-Barbera [28] and Christos et al. [39].

Figure 11: Surface tension of hydrazinium nitrate/hydrazine solutions at various hydrazinium nitrate concentrations as a function of temperature. (Reproduced and modified from [3].)

1.2.7 Optical Properties of Hydrazinium(1+) Nitrate

1.2.7.1 IR Spectra of Hydrazinium Nitrates

The IR spectrum of HN crystals shows absorption bands at 3.1(s), 6.6(w), 7.2(vs), 9(s), 10.3(s), and 12.1(s) μm (Figure 12) [9].

Hydrazinium nitrate in hydrazine solution shows peaks at 3.3, 3.6, 3.9, 4.0, 4.6, 4.8, 7.7, and 12 μm . These absorption bands are very similar to those of dry HN. HN has been found in the reaction product of hydrazine and red fuming nitric acid under simulated rocket conditions and identified by its IR spectrum [46]. These spectra were unfortunately taken in Nujol or hexachloro-1,3-butadiene mulls, which clutter the spectra with extraneous absorption peaks.

Additional information on IR spectra of HN, typically for the range 2–15 μm , is available for $\text{N}_2\text{H}_5\text{NO}_3$, $\text{N}_2\text{H}_5\text{NO}_2$, and $\text{N}_2\text{H}_6(\text{NO}_3)_2$ from Miron and Perlee [13], and additional data for HN are available from Perlee et al. [47] and Saad et al. [48].

Figure 12: Infrared spectrum of hydrazinium nitrate. (Reproduced and modified from [9].)

1.2.7.2 Refractive Index of Hydrazinium Nitrate

The refractive indices of crystalline α -hydrazinium nitrate in the directions of the three optic axial angles with light at a wavelength of $5893 \text{ \AA}$ at 298 K are: $\alpha = 1.458 \pm 0.003$; $\beta = 1.605 \pm 0.004$; $\gamma = 1.620 \pm 0.003$ [11].

Refractive indices of 36 mixtures in the ternary system $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{NO}_3/\text{H}_2\text{O}$ were determined [30]. For 5% HN mixtures, the refractive index $n_D^{273\text{ K}}$ decreased from 1.4678 at 5% water to 1.4375 at 30% H_2O . Likewise, starting with 29% HN and 5% H_2O , the refractive index decreased from 1.4766 to 1.4418 when going to 29% HN and 30% H_2O . When represented graphically, in-between values of mixtures with 10–25% HN did not always fall on nice straight parallel lines, but this may have been caused by the scatter of the data and/or uncertainty about the composition of the mixtures. The refractive index alone is insufficient to serve as an analytical tool for ternary mixtures but can be used for binary mixtures.

Hydrazinium nitrate is transported and stored as an aqueous solution. The refractive index determination of HN/water solutions is an easy method of determining the HN content (in the absence of other contaminants); see Figure 13.

1.2.8 Proton Magnetic Resonance Spectra of Hydrazinium Nitrate

Hydrazinium(2+) dinitrate is very hygroscopic and deteriorates rapidly when exposed to room air. The first nuclear magnetic resonance (NMR) investigation of this salt showed that it contains the $\text{N}_2\text{H}_6^{++}$ ion similar to the one in hydrazinium(2+) sulfate [49]. It was estimated that the $\text{H}\cdots\text{H}$ distance in the $\text{N}_2\text{H}_6^{++}$ ion is $1.71 \text{ \AA}$, assuming a symmetrical staggered configuration. If tetrahedral angles are assumed, this leads to a $\text{N}-\text{H}$ distance of $1.048 \text{ \AA}$. In continuation of this study, NMR line widths

Figure 13: Refractive index of aqueous hydrazinium nitrate solutions. (Reproduced and modified from [3].)

of $N_2H_6(NO_3)_2$ have been measured at 90 K and at room temperature [50]. A line width transition occurs near 150 K and this has been interpreted as a reorientation of the $N_2H_6^{++}$ ion about the N – N axis.

Harrell and co-workers were able to obtain proton NMR spectra on cooled samples at temperatures from 106 to 360 K [51], which indicated the existence of at least two, possibly even four different phases in analogy to hydrazinium(1+) nitrate for which two phases are known. These two known phases were again confirmed in proton NMR measurements at temperatures from 140 to 362 K. The relaxation due to H_2N —motion results from dipole-dipole interactions with the nitrogen nucleus of the H_2N —groups and with protons of the H_3N^+ — group. Similar observations were made with $N_2H_5NO_3$ [52].

1.2.9 Electron Spin Resonance Spectra of Hydrazinium Salts

The spin-lattice relaxation times of protons in polycrystalline hydrazinium(2+) chloride, $N_2H_6Cl_2$, hydrazinium(2+) nitrate, $N_2H_6(NO_3)_2$, hydrazine hydrate,

$\text{N}_2\text{H}_5\text{OH}$, and hydrazinium(2+) sulfate, $\text{N}_2\text{H}_6\text{SO}_4$, have been measured at 60 MHz as a function of temperature between 140 and 450 K [53, 54]. Relaxation time T_1 passed through a minimum of 21.6 ms for each of the first three compounds. The temperature dependence of T_1 was found to be characteristic of a dominant relaxation mechanism, reorientational motion of NH_3^+ groups about the N–N bond direction. The experimental value $(T_1)_{\min} = 21.6$ ms agreed with the estimated value for the first three compounds.

1.2.10 Thermodynamic Properties of Hydrazinium(1+) Nitrate

Because crystalline HN exists in at least two different phases, which differ in their physical and thermodynamic properties, it is important that the phase condition be included in all reported data. At room temperature (298 K), the only stable phase of HN is the α phase. So in most cases one must assume that the reported data are for the α phase of HN.

1.2.10.1 Heat Capacity of Hydrazinium(1+) Nitrate

The heat capacity of solid hydrazinium(1+) nitrate was measured from 220 to 370 K using two different methods with good agreement [17]. The smoothed data are summarized in Table 8. The authors fail to state whether these heat capacity data are for the alpha or beta modification of HN. Because the beta modification is unstable and voluntarily converts to the alpha modification, it is assumed that all the data are for the alpha modification.

Table 8: Smoothed heat capacity of solid hydrazinium(1+) nitrate.

Temperature, K	Heat capacity, $\text{J mol}^{-1} \text{K}^{-1}$	Temperature, K	Heat capacity, $\text{J mol}^{-1} \text{K}^{-1}$
220	110.5	290	138.7
230	114.4	300	143.6

1.2.10.5 Enthalpy of Solution of Hydrazinium(1+) Nitrate

The enthalpy of solution of HN in water is endothermic (Tables 12 and 13), similar to that of AN, but not as strongly endothermic that one would want to use this salt in ice packs to treat athlete's injuries on the football field (where AN is indeed used).

Table 12: Standard enthalpy of dissolution of hydrazinium nitrate in comparison with that of other oxidizers.

1.2.11 Molecular Structure of Hydrazinium Nitrate

Hydrazinium(1+) nitrate exists in two crystalline forms, the α and the β modification. The β form is unstable, and few properties other than its melting point and the refractive index are known. α -Hydrazinium(1+) nitrate melts at 343.6 K [9, 11], and the β modification melts 8° lower at 335.6 K. Even antiquated melting points reported 100 years ago differ only by fractional degrees [12]. A melt of HN supercools readily and results in the unstable β form. The conversion from the β form to the α form is exothermic and monotropic. The heat of conversion is 8.36 kJ/mol (2.0 kcal/mol), as measured by differential scanning calorimetry. No additional thermal phase transformations could be found between the $\alpha \rightarrow \beta$ transition temperature and the melting point, in contrast to AN, which undergoes several phase changes.

The monoprotinated hydrazinium cation forms several types of hydrogen bonds with surrounding nitrate ions. Stronger ones, in which the hydrogen atoms attached to the protonated nitrogen atom take part, link cations and anions into layers. Less strong hydrogen bonds, with participation of H atoms attached to the non-protonated N atom, link the layers into a three-dimensional structure. In addition to hydrogen bonds, short contacts of 2.8607 Å were found between O and N atoms of neighboring nitrate anions. Such contacts can correspond to a weak intermolecular interaction similar to that in organic nitro compounds. Crystal structures of HN and several other hydrazinium salts are listed in Table 14.

1.2.12 Computational Analysis of the Structures of Hydrazinium Nitrates

Hydrazinium nitrate is of interest as an ionic liquid. It was shown that it is quite difficult to achieve an accurate and consistent description of the modified HN ionic crystals [71]. In further work, a systematic force field method was developed that can describe crystal structures for these modified HN ionic materials [72, 73]. In addition, the developed polarizable force field methods were extended to other anions such as azide N_3^- , dicyanamide $\text{N}(\text{CN})_2^-$, and 5-azidotetrazolate CN_7^- in addition to NO_3^- , using seven high-nitrogen-content ionic crystals. After force field validation, Molecular Dynamics simulations were used employing the developed force field method to perform initial investigations of the mechanical properties in the crystalline system and investigate the structural interactions of cations and anions in the crystalline (and in some cases liquid) state. For the seven crystals that were simulated, the largest deviations were seen in those that have the smallest anions. For the $[\text{N}_2\text{H}_5][\text{NO}_3]$ crystal the volumetric deviation between the two sets of data was only ~6% (Table 15). Similar data were obtained for MMH nitrate and UDMH nitrate.

1.3 Chemical Properties of Hydrazinium Nitrate

1.3.1 Reactions of Hydrazinium Nitrate

In many applications, such as in the reprocessing of spent nuclear reactor fuel rods, HN is used in strongly acidic solutions with nitric acid, often together with HAN, to remove HNO₂ and nitrite ion, which interfere with isotope separation. This opens up the possibility that the hydrazinium cation will become oxidized by nitrate anions and destroyed in an exothermic reaction sometimes catalyzed by metal ions that are also in the solution. HNO₂ and HN₃ are intermediates in this reaction.

In order to determine the temperature threshold for this reaction, initiation temperatures and heats of this reaction, the effects of impurities on initiation temperature and self-accelerating reaction were measured in a pressure vessel type reaction calorimeter [74]. This reaction may also be accelerated by external ultrasound used to accelerate the dissolving of the spent reactor fuel rods.

The effect of ultrasound ($f = 20$ kHz) on the decomposition of HN was investigated in a nitric acid medium [75]. The kinetics of N₂H₅⁺ decomposition and initial HN₃ formation increase in a linear manner with the HNO₃ concentration (from 1 to 6 M) and with the ultrasonic intensity (from 0.5 to 3.1 W/cm²). HN₃ is volatile and diffuses into the cavitation bubbles where it decomposes. The variation of the steady-state HN₃ concentration with the HNO₃ concentration and the ultrasonic intensity suggests the existence of a non-explosive HN₃ thermal decomposition mechanism in the cavitation bubble under the effect of ultrasound. It was also observed at ultrasonic intensities exceeding 3.5 W/cm² that the decomposition of HN₃ led to the accumulation of NH₄⁺ in solution. See also [76].

1.3.2 Analysis of Hydrazinium Nitrate

Hydrazinium nitrate is rarely used in the solid state. Most analytical methods for HN are for HN solutions. Nitrate in aqueous solutions can be determined gravimetrically with nitron, which also precipitates perchlorate if any is present in addition to nitrate.

Hydrazinium nitrate in liquid explosives can be analyzed by titration in acetic acid as the solvent [77–79]. Hydrazinium(1+) nitrate has been determined as a base by non-aqueous titration in glacial acetic acid. The titrant was 0.05-N perchloric acid in glacial acetic acid, which must be prepared without acetic anhydride. Small amounts of water increased the solubility of hydrazine nitrate, but reduced the sensitivity of the method.

The mass spectrum of HN shows peaks at a mass-to-charge-ratio (m/e) of 63 (HNO_3^+), 46 (NO_2^+), 28–32 (N_2^+ , N_2H^+ , N_2H_2^+ , N_2H_4^+ plus possibly NO^+ and O_2^+), and 16 (O^+ or possibly NH_2^+) [46].

1.3.3 Thermal Stability of Hydrazinium Nitrate

1.3.3.1 Decomposition of Hydrazinium Nitrate

Hydrazinium nitrate is thermally unstable and begins to decompose shortly after it melts. In all states, solid or liquid, HN is detonable and constitutes a substantial risk for accidents [80, 81].

1.3.3.2 Slow Controlled Decomposition of Hydrazinium Nitrate

The weight loss of 1-g samples of HN after 6-min. exposure to temperatures from 453 to 523 K increased from barely noticeable at 453 K to 80% conversion at 523 K [82]. The weight loss remained below 5% per 6-min exposure until the temperature reached 493 K. Ammonium nitrate subjected to the same test for comparison decomposed much more slowly, at approximately only half the rate of HN. The addition of potassium dichromate to molten HN at 373 K caused immediate decomposition with an explosion.

When studying the thermal decomposition of hydrazinium(1+) nitrate in a microcalorimeter, it was noted that the reaction rates and the ultimate products are very dependent on the mass loading density m/V and the temperature profile in the reaction vessel [16]. When the reaction was carried out in evacuated and sealed 1.8- to 2.5-mL vials at uniform temperature, the final pressure in the vials was of the order of 1.01–2.02 MPa. The thermal decomposition of HN is self-accelerating. The rate of self-acceleration increases with m/V . The rate equation is

$$\frac{d\eta}{dt} = k_1(1-\eta)^2 + k_2\eta(1-\eta)^2$$

where η is the fractional conversion and k_1 and k_2 are constants; k_1 is a real constant, whereas k_2 increases with m/V . The temperature variation of k_1 when plotted as $\log k_1$ versus $1/T$ is expressed by

$$k_1 = 10^{12.2} e^{\frac{-38000}{RT}} \quad \text{s}^{-1}.$$

For a mass loading of $m/V = 10^{-3} \text{ g/cm}^3$, k_2 is expressed by

$$k_2 = 10^{7.8} e^{\frac{-26500}{RT}} \quad \text{s}^{-1}.$$

The activation energy obtained by numerical integration of the rate curves is 141.4 ± 5.86 kJ/mol (33.8 ± 1.4 kcal/mol). The solid residue left behind in sealed vials weighed approximately 65% of the HN. It melted at 443 K and has been analyzed as AN, formed at the rate of 0.75 mol of AN per mol of initial HN. The decomposition reaction can be written as follows:

When the thermal decomposition is carried out in a large vessel that is not at uniform temperature, the reaction obeys different kinetics. Some of the HN sublimes and condenses on the colder walls of the vessel, and the reaction continues until the sample in the hot part of the vessel disappears altogether (no AN residue). In agreement with other investigators [82], Rubtsov and Manelis [16] explain the kinetics by assuming that HN first dissociates into hydrazine and nitric acid. The hydrazine then decomposes into ammonia and nitrogen. Nitric acid on the other hand decomposes into nitrogen dioxide, oxygen, and water. The nitric acid decomposition products quickly react with hydrazine under the formation of H_2O , N_2O , NH_3 , and N_2 . This mechanism is supported by the autocatalytic effect of hydrazine or hydrogen chloride. Toward the end of the reaction in sealed vessels, the excess ammonia pressure retards the further decomposition of AN.

By comparison, pure hydrazine decomposes in the temperature range investigated only very slowly. At 475 K the rate of heat evolution of 100 mg of pure hydrazine was so slow that it was at the limit of sensitivity of the calorimeter. When HN was added to liquid hydrazine, however, the rate of decomposition of hydrazine increased sharply. The decomposition rate is proportional to the amount of HN

$$\frac{dc}{dt} = k [\text{N}_2\text{H}_4] [\text{N}_2\text{H}_5\text{NO}_3].$$

Various hydrazine nitrates may form as the result of an incomplete reaction of hydrazine with dinitrogen tetroxide in a rocket engine. Accumulation of such residues and sudden ignition may cause destructive pressure spikes in rocket engines. Vacuum thermal decomposition of hydrazinium(1+) nitrate (= HN) and hydrazinium(2+) nitrate (= "HN-2") with simultaneous mass spectrometry resulted in the evolution of nine identifiable species [19, 83]. When these salts are decomposed in a differential thermal analysis (DTA) apparatus in a vacuum instead of at ambient pressure, the terminal exotherm is replaced by a large endotherm. Apparently, the heat of vaporization of the substantial amounts of water formed per

overshadows all other events. The major products were water, NO, and N_2 . Minor products were N_2O , NO_2 , NH_3 , HN_3 , H_2 , and O_2 . Some N_2H_4 and HNO_3 were also found. This is evidence of dissociation without decomposition. Water and N_2O were the first

decomposition products detected while raising the temperature at around 400 K. NO and NO₂ did not appear before the temperature had reached 470 K. Decomposition was complete at 528 K. The vacuum decomposition DTA/mass spectrometry (MS) of HN-2 showed water formation at a lower temperature (approximately 423 K) accompanied by the first endotherm in the thermogram. In addition, a considerable quantity of NO₂ was evolved at these temperatures. In fact, NO₂, which was only a minor product of HN decomposition, became a major product in the HN-2 decomposition, together with H₂O, NO, and N₂. A larger amount of HN₃ was also produced.

The weight loss rate of molten hydrazinium(1+) nitrate was measured with 20-mg samples having surface areas of approximately 0.2 cm² [9]. At 473 K, the rate was 0.4 wt.%/min, and at 423 K it was 0.06%/min. The weight loss can be attributed entirely to a dissociation process. In other experiments, when HN was heated intermittently to 383 K for a total of 315 h, the average weight loss was 8×10^{-5} %/min [84]. The weight loss rate of a 1-g sample of HN at 500 K was linear with time [13]. Hydrazinium(2+) dinitrate (HN-2) is less stable than HN. It begins to lose mass below its melting point of 353 K. If heated slowly, it melts at 353 K; if heated rapidly, it melts at 376 K; if heated in a water bath at 373 K, HN-2 decomposed, leaving a residue of AN. The reaction of HN-2 with hydrazine at 298 K is exothermic with 63 kJ/mol HN-2 (15 kcal/mol).

The DTA of N₂H₅NO₃ showed a melting endotherm at 343 K and additional endotherms at 451 and 513 K [15]. Other investigators observed a melting endotherm at 345.4 K and an exotherm at 363 K [85] and for α-N₂H₅NO₃ they observed melting at 343.86 K [18].

The thermal decomposition of hydrazinium(1+) nitrate starts soon after melting [86]. See also [17, 87].

Addition of hydrazinium(1+) nitrate to HAN suppressed the decomposition of HAN for several hours [88]. In one instance a sharp explosion occurred at 413 K. Mass spectrometric analysis showed hydrazoic acid as the pyrolysis product, in particular if hydrazinium(2+) dinitrate instead of the (1+) salt was added to the HAN. The (2+) salt shortened the induction period and accelerated the decomposition reaction of HAN.

1.3.3.3 Decomposition of Hydrazinium Nitrate Solutions

Concentrated aqueous HN solutions are not very stable. The thermal stability of concentrated (1 to 5.8 molar) aqueous HN solutions was studied at 303 K as a function of pH and container size [89]. Decomposition as indicated by gas evolution in glass vessels with three different diameters was measured for 30 days at four different concentrations and initial pH values ranging from 3.3 to 5.4. The pH dropped with progressive HN decomposition. In the early phase of the reactions, oxygen in the air space above the samples was consumed and some of the subsequent tests were performed under argon instead of air. Surprisingly, typically 2 to 6% of the HN decomposed during only 1 month of storage at 303 K. One must also anticipate the formation of HA

as a decomposition product. Specifications for commercial sources for 30% or 50% HN solutions limit the allowable azide concentration to 0.01% max. An Arrhenius plot based on gas evolution rates of 1-molar HN solutions at 303 to 348 K and fitted to a first-order rate equation of

$$k = 6.03 \exp(-5300/RT) d^{-1}$$

gave an activation energy of approximately 22 kJ/mol.

Both hydrazinium(1+) nitrate and HAN are shipped commercially in large quantities in aqueous solutions, but the allowable concentration is limited. HN along with HAN nitrate in nitric acid solutions is used in the plutonium uranium reduction extraction (PUREX) process for the reprocessing of spent nuclear reactor fuel elements and the separation of uranium and plutonium and other fission products. There is concern about accidental runaway reactions during the mixing of the reactants in the PUREX process and a series of investigations was made about the exothermicity of reactions involving HN and increasing amounts of nitric acid [90, 91].

The thermal properties of hydrazinium ion in nitric acid solution, which is used for preventing the oxidation of extracted plutonium, were studied by thermal analysis of mixtures under various conditions. From the results of DSC it was revealed that the vessel material has an influence on the thermal decomposition of hydrazine. It was also found that hydrazine reacted with nitric acid in an autocatalytic manner, and the concentration of nitric acid has a strong influence on the thermal hazard of HN and nitric acid mixtures [92, 93]. The onset of thermal decomposition of HN solutions was shifted to lower temperatures by the presence of excess nitric acid.

The thermal stability and ignition behavior of aqueous solutions of HN were measured at pressures up to 4 kbar and temperatures up to 830 K [94]. The technique produced different kinetic data for the two methods of analysis used. The extrapolated rates bracketed the one estimated from detonation experiments.

The effect of ultrasound ($f = 20$ kHz) on the decomposition of aqueous HN solutions was investigated in a nitric acid medium [75]. The kinetics of $N_2H_5^+$ decomposition and initial HN_3 formation increased in a linear manner with the HNO_3 concentration (from 1 to 6 M) and with the ultrasonic intensity (from 0.5 to 3.1 W/cm²). Both rates were equal to that of HNO_2 formation in the absence of $N_2H_5^+$, indicating that the $N_2H_5^+$ decomposition mechanism is the same as that observed during the reaction between HNO_2 and $N_2H_5^+$ without ultrasound. The variation of the steady-state HN_3 concentration with the HNO_3 concentration and the ultrasonic intensity suggested the existence of a non-explosive HN_3 thermal decomposition mechanism in the cavitation bubble under the effect of ultrasound. It was also observed at ultrasonic intensities exceeding 3.5 W/cm² that the decomposition of HN_3 led to the accumulation of NH_4^+ in the solution.

1.3.3.4 Flash Pyrolysis of Hydrazinium Nitrate

The US Bureau of Mines (USBM) “Bruceton up and down” method has been applied to determine the ignition temperature of hydrazinium(1+) nitrate on a hot plate [95]. The 50% probability of ignition was reached at 580 K.

When HN was heated rapidly at atmospheric pressure in air, it decomposed explosively at 680 K [9].

Rapid thermolysis of HN under argon pressure of up to 500 psia (3.4 MPa) and heating rates of 75 and 105 °C/min and analysis of the gas products by Fourier transform infrared spectroscopy (FTIR) showed that the first gas product is N₂O, followed by NH₃ and even subliming NH₄NO₃ [96]. Hydrazoic acid was a major intermediate product. NO and H₂O were among the last products to appear.

1.4 Strand Burning of Hydrazinium Nitrate

1.4.1 Strand Burning of Hydrazinium Nitrate

Dry HN packed into glass tubes of 10, 15, and 20 mm in diameter could not be ignited by an incandescent nichrome wire [82]. While the wire was hot, HN only melted, and the melt burned for 3–5 mm, but combustion soon ceased. Even HN melted and heated to 353 K did not burn. Only after the melt temperature was increased to 373 K did HN burn in a 20-mm tube at 0.073 cm/s. When 10% K₂Cr₂O₇ was added to HN, the powder would even burn at ambient temperature and pressure with a rate of 0.105 cm/s. With less K₂Cr₂O₇ catalyst added, combustion was accordingly slower, 0.05 cm/s at 0.5% K₂Cr₂O₇.

The burning rate of 7-mm strands of HN pressed into plexiglass tubes is dependent on the chamber pressure according to

$$u = 0.33p^{0.82}$$

where u is the burning rate in mm/s and p is the pressure in atm. The addition of potassium, sodium, or lithium nitrate, and surprisingly also potassium chloride, strongly increased the combustion rate but had a weak effect on the lower limit of stable combustion [62]. In the range of 3.84 mass-% additive, lithium nitrate enhanced burning most actively, quintupling the strand burning rate at 101 MPa from 14 to 44 mm/s. If more than 10–15% additive was added, the relative increase passed through a maximum and dropped to the initial value beyond 20%. Molten HN at 373 K at pressures above 404 kPa burned with high velocity (30–100 mm/s), with a strong dependence on pressure, and burning was accompanied by much spattering of unburned material. The additives accumulated on the surface of the burning material, retarding evaporation and allowing a more compact flame front.

Cast instead of tamped or pressed HN and HN-AN was used in a study of surface temperatures of burning solid propellants. The HN and HN-AN eutectics were used as model substances because the melt surface gives a well-defined surface tempera-

ture [97]. Both HN and 32 mol% AN/68 mol% HN (melting point 316 K) castings had to be catalyzed with 1.5 mass-% Cr_2O_3 catalyst, which was mixed in at temperatures a few degrees above the melting point before the cylinders were allowed to solidify in glass tubes as molds. An array of thermocouples was embedded in the cast grain, which recorded the passing of the combustion front. The temperature would level off while the melted zone was passing through. Burn rates of 0.25–0.78 cm/s at 0.68–5.35 MPa were typical for catalyzed AN-HN, whereas catalyzed HN would burn much faster, 1.2 cm/s at 41 bars. The average surface temperature of burning AN-HN was 580 and 468 K for HN by itself.

The surface temperature in the combustion wave of HN, as well as in ammonium dinitramide (ADN), AN, and ammonium perchlorate (AP), is controlled by a dissociation process, similar to that postulated for other onium salts [98].

1.4.2 Strand Burning of Hydrazinium Nitrate Solutions

Hydrazinium nitrate solutions in water and/or hydrazine have been thoroughly evaluated as monopropellants and liquid gun propellants (See *Encyclopedia of Monopropellants*, chapter “Hydrazine Monopropellants”). Strand burning rates have been measured for a wide range of compositions and up to very high chamber pressures.

At Naval Ordn. Lab., White Oak, MD, two burning rate setups were used to characterize the HN blends by burning rate and impetus, one was an 840-cm³ bomb operating at 34.4 to 206 MPa (5000 to 30000 psi) and another operating at 206 to 688 MPa (30000 to 100000 psi). The progress of the flame front through the liquid strand contained in a meltable plastic tube was monitored by break wires that melted when the flame consumed them [30, 99, 100]. In addition to burning rate studies of HN by itself, burning rates of HN with binders and nanometal powders have been measured [101, 102].

1.5 Safety Properties of Hydrazinium Nitrate

1.5.1 Drop Weight Impact Sensitivity of Hydrazinium Nitrate

Most of the more energetic hydrazinium salts are drop-weight sensitive (Table 16). HN, although never handled as a dry solid in bulk quantities, is an important constituent of liquid propellants and liquid explosives. It may crystallize from such solutions on inadvertent evaporation of the solvent. HN was found in the residues of incomplete combustion of hypergolic storable propellants. Its drop-weight sensitivity has been determined by numerous investigators using different experimental methods. Drop-weight sensitivity data reported in the literature for HN differ widely, not only because of the different experimental techniques used, but also because the very hygroscopic samples may not have been totally dry.

Table 16: Drop-weight impact sensitivity of hydrazinium salts.

BAM = Bundesanstalt für Materialprüfung, Berlin, Germany, Picatinny = Picatinny Arsenal, Dover, NJ, RDX = 1,3,5-trinitro-1,3,5-triazacyclohexane, USBM = U.S. Bureau of Mines, Pittsburgh, PA

Medard [84] measured values of 200–250 kg cm in an unspecified apparatus, which seems to be unrealistically insensitive.

A drop height of 10 cm with a 2-kg weight in a Picatinny apparatus gave a 50% probability of ignition of HN crystals [103, 104]. In the same apparatus, for comparison, the 50% point for nitroglycerin was 2.5 cm, 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX) 17.8 cm, methylhydrazinium nitrate 38 cm, and ammonium perchlorate (AP) 46 cm.

The impact sensitivity of HN (20 to 25 cm, 50% fires, 2-kg weight) was independent of the water content over a range from 0.01 to 1.71 mass-% H_2O , or the type of anvil surface used (bare anvil or grit paper). HN was only slightly hygroscopic at relative humidities up to 52%.

Using the “Bruceton up-and-down” method, the 50% probability for ignition was reported as 175 kg cm in a cup and plunger and 50 kg cm in an Explosives Research Laboratory (ERL)-type 12 tool [9]. A lower value of 32 kg cm in the same tool was obtained on a different sample.

1.5.2 Shock Sensitivity of Hydrazinium Nitrate

Hydrazinium nitrate could not be detonated or even caused to burn at atmospheric pressure by electrically heated wires [9, 82, 109]. When initiated by a blasting cap or boosted with a high explosive, molten, granular or cast/pressed solid HN detonates. Depending on the mode of initiation, high-velocity detonation (HVD) or low-velocity detonation (LVD) could be observed. In a wedge-shaped container, the detonation may start as HVD (7600–8500 m/s) and may transition to LVD (1400–2400 m/s) after the sample thickness drops below the critical thickness for HVD. Some of the results (also for HN-water and HN-hydrazine mixes) are summarized in Table 17. The critical film thickness is of practical importance if an explosive is sought that is able to propagate detonation into narrow crevasses in rock for explosive fracturing. For monopropellant applications, a thin critical diameter is undesirable because combustion may burn back from the combustion chamber into the manifold or even the propellant tank, which would be disastrous.

Hydrazinium nitrate has been identified as one of the constituents of residues found in dinitrogen tetroxide (NTO)/Aerozine-50 rocket engines after very short vacuum pulse mode operations. These residues are the suspected cause of pressure spikes when they light off and detonate during subsequent pulses. This was a major concern during the development of the Apollo moon landing project in the 1960s. Leaking valves may allow chunks of frozen, unreacted propellant to accumulate in the chamber during idle periods in the vacuum and cold of outer space. Physical properties and detonability of HN mixtures were investigated in an effort to explain hard start and spiking phenomena. The US Bureau of Mines conducted a very thorough evaluation of the hard start phenomena in NTO hypergolic bipropellant engines with hydrazine-type fuels [110]. Next, fuel samples were tested in a ballistic mortar suspended from

a pendulum, with and without NTO, air, or oxygen added as oxidizers [111]. All tests were conducted in triplicate.

When liquid fuels and liquid NTO were encapsulated separately in glass vials, loaded into the mortar, and crushed by firing a cap, the trinitrotoluene (TNT) equivalencies rose to 170%. Improved mixing and highest TNT equivalencies were achieved when the glass vials were coaxial instead of adjacent to each other. In an effort to study the hazard of frozen accumulations of leaked propellants, the fuels and NTO were frozen in liquid nitrogen, pulverized, and carefully mixed at LN_2 temperature, and small 20- to 40-mg samples were loaded into a DSC apparatus. The instrument began taking measurements only after the samples had warmed to 173 K. Beginning exotherms were observed at 205 K and the reaction became very rapid at 218 ± 3 K for $\text{NTO}/\text{N}_2\text{H}_4$. The frozen propellant thawing tests were then repeated on a large scale with 1- to 60-g samples. Typically on thawing there was a violent reaction. Only two out of dozens of samples detonated and pulverized the glass beaker. Small samples thawing slowly were shown to contain hydrazinium(1+) nitrate, identified by its IR spectra. Another segment of the USBM study prepared pure samples of various hydrazinium salts and their solutions in hydrazine or water to determine their physical properties and explosive hazards [13]. Samples of granular (0.7 g/cm^3) and cast (1.6 g/cm^3) HN were subjected to impingement of a shock wave generated by detonation of a gaseous $\text{O}_2/\text{C}_2\text{H}_4$ mixture at varying initial pressures. The initiation pressure spike was between 48 and 434 MPa (475 and 4300 atm) and the elicited response of the HN was detonation at 1.9 to 2.7 mm/ μs and detonation pressures from 68 to 1236 MPa (680 to 12240 atm).

One of the questions was whether the material accumulating in rocket engines was capable of supporting detonation in a thin film, as found in these engines [39]. A trough filled with liquid explosive and slanted gave a wedge-shaped partially confined geometry of the explosive specimen. The thin-film test, summarized in Table 17, showed that molten HN and HN solutions in water or hydrazine with more than 80% HN are capable of supporting a stable LVD in films as thin as 0.25 mm (0.01 in). The detonation, initiated by two 25-g tetryl pellets, would typically start HVD, but convert to LVD when the wedge thickness dropped below the critical film thickness for HVD. In view of the suspicious engine deposits that prompted this investigation, it was concluded that at least 1 g of HN would have to accumulate in the engine to do any structural damage, a much larger amount than what has been removed from pulsed engines in any instance.

The low melting point of HN (343 K) is advantageous for using it and studying it as a liquid explosive. The molten material is easily mixed with other materials (e.g., AN), cast in shaped charges, or used as a liquid explosive [112].

A study of the effect of water on the critical diameter of molten HN showed that the critical diameter at 348 K increases from 4 to 28 mm with 0–24% water in the mixture [113]. Beyond 24% H_2O , the critical diameter increases very rapidly. It was noted that molten HN and its aqueous solutions are capable of detonating at different velocities:

Table 17: Detonation velocity and critical film thickness of hydrazinium nitrate and its mixtures (at 348 K).

Composition	HN Mass-%	HVD		LVD	
		Velocity m/s	Thickness cm	Velocity m/s	Thickness cm
HN	100	8500	0.127	1400	≤0.025 ^a
HN/H ₂ O	85	7600	0.305	2400	≤0.025
HN/H ₂ O	75	Not observed		2100	0.33
HN/H ₂ O	65	No propagation		No propagation	
HN/N ₂ H ₄	80	8600	0.076	1800	≤0.025
HN/N ₂ H ₄	60	8200	0.076	Not observed	
HN/N ₂ H ₄	40	7800	0.254	2200	0.076
HN/N ₂ H ₄	20	No propagation		No propagation	

^a0.025 cm represents the limit of resolution of the apparatus

Data source: [9, 39]

at a high (normal) velocity near 8 km/s and at a low velocity of the order of 2 km/s. Above a critical diameter, the detonation always propagates at a high velocity. Below the critical diameter, or with higher water content, the mixture may detonate with a low-order velocity as long as it is still close to the borderline, or it will not detonate at all. The effect of the water diluent in the critical diameter of HN can be expressed by

$$d^{*'} = \alpha d^* \exp \left[\left(\frac{1 - \alpha}{\alpha} \right) \frac{A}{RT} \right]$$

where $d^{*'}$ is the critical diameter of the mixture, d^* is the critical diameter of pure HN, and α is the mass fraction of liquid explosive in the mixture. The ratio A/RT is equal to 7.1–7.5 for the HN–H₂O system. The detonation velocity of molten HN at the critical diameter is 8150 m/s and slightly higher in larger (four- to fivefold d^*) charges, 8380 m/s. The density of liquid HN at 348 K is 1.544 g/cm³. The detonation velocity of solid HN compressed to the same density is 8220 m/s. At high densities the detonation velocity of HN is equal to or even higher than that of RDX, although the heat of explosion of HN is less than that of RDX.

1.5.3 Shock Sensitivity of Hydrazinium Nitrate Solutions

Hydrazinium nitrate that is intended for use in nuclear reactor fuel element reprocessing and uranium/plutonium separation is usually shipped as a 30% aqueous solution. It has received a shipping permit as Toxic Liquid, Inorganic, N.O.S. (Hydrazine Nitrate Solution) under UN Number: 3287, Class: 6.1, P.G.: III; Label Code: 6.1. See also [114, 115]. There was concern that in large bulk containers this solution might still be detonable. One must remember that the data in the graph in Figure 14 were only obtained in

1-in diameter charges and any geometry above this dimension might still be detonable in a wider range of compositions. This ternary graph with the detonability boundary drawn in has been used extensively in the selection of low-freezing hydrazine monopropellants (see *Encyclopedia of Monopropellants*).

Figure 14: Detonable range in hydrazine/hydrazinium nitrate/water ternary mixtures. (Reproduced and modified from [9].)

1.5.4 Friction Sensitivity of Hydrazinium Nitrate

In the friction sensitivity test apparatus of the West German Institute for Materials Testing (BAM), HN was negative at up to 36 kg_f, but hydrazinium(1+) perchlorate (HP1) was positive at 1 kg_f [107].

1.5.5 Electrostatic Sensitivity of Hydrazinium Nitrate

Hydrazinium nitrate in the dry state is readily initiated by a small discharge of static electricity as the powder is poured from one container to another. HN explosions can be initiated by a hot wire even in HN solutions. Autoignition may occur on heating at 830 K, also under elevated pressure in a pressure bomb [94]. This method can study the ignition in exothermic systems under high pressure and temperature. Experimental details were given for pressures up to 4 kbar and temperatures up to 2000 K. The technique applied to aqueous hydrazine mononitrate had a temperature limit of 830 K and produced different kinetic data for the two methods of analysis used. The extrapolated rates did, however, bracket that estimated from detonation experiments.

The maximum energy for zero probability of ignition using a potential of 5000 V is 12.5 J [107].

1.6 Explosive Performance of Hydrazinium Nitrate

1.6.1 Detonation Velocity of Hydrazinium Nitrate

Explosives can be subdivided into two groups, depending on the nature of critical diameter and its dependence on loading density. Group I explosives (such as pentaerythritol tetranitrate [PETN], tetryl, TNT) exhibit a decrease in critical diameter with an increase in loading density. Group II explosives (such as HN or AP) exhibit an increase in critical diameter with an increase in loading density. In one study, 20-mm-diameter pellets of HN pressed to densities of 1.650–1.676 g/cm³ and initiated with a variety of methods (booster explosives plus flyer plates) detonated with shock velocities of 5.42–6.69 mm/μs and particle velocities of 0.8–2.44 mm/μs [116]. Other pressed pellets were machined to the shape of a wedge. The critical diameter below which detonation no longer propagated could be determined from high-speed photographs taken with a streak camera. Particle velocities and shock pressures were calculated by the impedance matching method. When plotting the shock velocity U versus the particle velocity u of HN, it was noted that the Hugoniot curve has two different slopes, with a distinct change of slope at $u = 0.86$ mm/μs. None of the two curves intersected the detonation pressure point. Below $u = 0.86$, the shock velocity obeyed Equation (1). Above $u = 0.86$, Equation (2) applied instead:

$$U = 1.2 + 4.9u \quad \text{Equation (1)}$$

$$U = 5.0 + 0.53u \quad \text{Equation (2)}$$

The shock pressure at the intersection was about 8 GPa as opposed to a Chapman-Jouguet (C-J) pressure of 30 GPa calculated from theoretical data. Calculated shock and particle velocities were 9.11 and 1.99 mm/μs respectively.

At equal granular density, HN powder detonates more slowly than hydrazinium(1+) azide (HA), 2115 m/s compared with 2460 m/s [117].

Unlike TNT, the critical diameter of granular-pressed HN increases with increasing loading density. Detonation velocity as a function of loading density exhibits a maximum at densities of 0.5–1.5 g/cm³ [36]. The infinite diameter curve giving the detonation velocity as a function of loading density is

$$D = 5.388(\rho_0) - 0.100$$

where D is the detonation velocity in mm/μs and ρ_0 is the density in g/cm³. At finite diameters of 1.27 to 4.14 cm, the D vs ρ_0 curves exhibit maxima. This behavior is to be expected of explosives whose critical diameter increases with increasing loading density, the reverse of the trend exhibited by common explosives such as TNT. The location of the maximum is dependent on the charge diameter ($D_{\max} = 4900$ m/s at $d = 1.27$ cm, 7300 m/s at $d = 2.54$ cm, and 7400 m/s at $d = 4.1$ cm). A charge measuring 1.27 cm in diameter pressed to 1.63 g/cm³ failed to detonate. With extrapolation to infinite charge diameter, an ideal detonation velocity for HN has been calculated from

these data to be 8500 m/s. This was in close agreement with predictions by the RUBY code (8660 m/s at 1.68 g/cm^3 to 5880 m/s at 1 g/cm^3). See also [118].

The detonation velocity and pressure of water-free HN pellets pressed to maximum density (1.68 g/cm^3) is dependent on pellet diameter (Table 18). The failure diameter of pressed HN pellets is between 20 and 30 mm.

Table 18: Detonation velocity of hydrazinium(1+) nitrate pellets.

Pellet diameter d , mm	Detonation velocity D , km/s	Particle velocity u_{CJ} , km/s	Detonation pressure P_{CJ} , GPa
60	8.92 ± 0.05	1.63 ± 0.03	24.4 ± 0.4
40	8.92 ± 0.05	1.63 ± 0.03	24.4 ± 0.4
30	7.61 ± 0.05	1.47 ± 0.03	18.7 ± 0.4
20	5.29 ± 0.05	—	—

Data source: [119]

For comparison, neat methylhydrazinium nitrate (“MMHN”) molten at 318 K contained in a 25-mm schedule 40 steel pipe underwent LVD ($2 \text{ mm}/\mu\text{s}$) when boosted with 50 g of tetryl and zero gap [120]. In a gap test, molten MMHN exhibited minimum film thicknesses of 1.5 and 1.8 mm for propagation at 2.2 to $2.3 \text{ mm}/\mu\text{s}$.

1.6.2 Theoretical Prediction of Detonation Velocity of Hydrazinium Nitrate

There are numerous hydrodynamic thermodynamic codes [121] that are capable of predicting the C-J detonation velocity and detonation pressure of condensed explosives. The main difference between the various codes is the type of the equation of state (EOS) used. Agreement between calculated and measured data for conventional, commercial explosives is sometimes poor owing to varying amounts of carbon formed in the experiment, but the computer programs now available are already a significant improvement over the “back-of-the-envelope” calculations based on the Kamlet and Jacobs technique. It was therefore of interest to compare the accuracy of computer predictions to measured data of explosives that do not contain any carbon, such as most hydrazine-based explosives. The detonation of HN was used to check the accuracy of computer predictions for carbon-free explosives because there were sufficient experimental data available to compare the two methods. The agreement of calculated data with experimental detonation velocities of HN was good [122, 123].

1.6.3 Detonation Velocity of Hydrazinium Nitrate Solutions

Ternary Mixtures. Hydrazine hydrate/HN mixtures containing 65, 68, 70, and 75 mass-% HN were tested in brass tubes measuring 10 or 20 mm in diameter and 150 mm long [124]. It is not quite clear from the translation whether the hydrazine

hydrate used contained 91.24% hydrazine hydrate = 58.4% N_2H_4 or not. For tests at elevated temperatures, the tube was surrounded by a temperature conditioning jacket of water with an outer diameter of 75 mm in a PVC tube. The density ρ of these mixtures at 293 K ranged from 1.322 to 1.388 g/cm³. The detonation velocity at 293 K in the 10-mm tube could be expressed as

$$D = 5.47\rho + 0.47$$

where D is the detonation velocity in km/s and the density ρ (a function of the HN concentration) at 293 K is entered in g/cm³ units. For a given mixture (e.g., the 68% HN mixture) in a 20-mm tube, the dependence of detonation velocity on temperature was

$$D = -0.0032t + 8.13$$

where D is the detonation velocity in km/s and t is the temperature in °C. The ideal detonation velocity in a tube of infinite diameter was extrapolated by plotting D versus reciprocal diameter and extrapolating to $1/d = 0$. The ideal detonation velocity of the mixes containing 65, 68, 70, and 75% HN was 7930, 8100, 8128, and 8318 m/s respectively.

Binary HN/Hydrazine Mixtures. The detonation velocity of hydrazine/HN mixtures in 20-mm plastic tubes increased from 8200 m/s at 55% HN to 8630 m/s at 90% HN (density 1.5 g/cm³) [125]. The curve representing the detonation velocity as a function of composition had not quite leveled off at 90% HN, and would most likely increase further if such mixtures could be kept in the liquid state. In analogous tests with HP instead of HN, the maximum detonation velocity under identical conditions was only 8400 m/s, but lead block indentations were higher than with HN.

Measured and calculated C-J detonation velocities (from two different authors), detonation pressures, and detonation temperatures of HN/hydrazine solutions containing 55 to 80% HN are summarized in Table 19. The agreement between the two sets of calculated data and the measurements is quite good.

Table 19: Measured and calculated Chapman-Jouguet detonation parameters of hydrazinium nitrate/ N_2H_4 solutions.

The detonation wave in liquid 21% hydrazine/79% HN detonations is not very luminous. The radiation emitted from the detonation front is insufficient to determine the temperature by black-body radiation as this can be done for the more carbonaceous detonation products of nitromethane [127]. The detonation wave is also not very strongly ionized, so that it is difficult to determine detonation velocities of hydrazine-based explosives by the make-circuit method with ionization probes. In spite of these difficulties, the detonation temperatures of nine different HN/hydrazine and HN/water solutions containing 55 to 95% HN was measured in comparison with conventional high explosives (TNT, RDX, tetryl) [128]. Measured and calculated detonation temperatures (using the Kihara-Hikita [KHT] EOS) for the HN/hydrazine mixtures containing 55 to 75% HN agreed moderately well, but measured detonation temperatures for the HN/water blends containing 80 to 95% HN were more than 1000 K hotter than the theoretical predictions. Obviously, the theory cannot quite handle the cooler-burning explosives yet. A comparison of different computational methods was based on calculating the dependence of the C-J temperature of TNT using five different EOSs (Becker-Kistiakowsky-Wilson [BKW], Jacobs-Cowperthwaite-Zwisler [JCZ3], Lennard-Jones Devonshire [LJD], Weeks-Chandler-Andersen [WCA4], and KHT) [126, 129].

Binary HN/Water Solutions. The detonation velocity of HN slurries and solutions contained in 50-mm diameter cylinders with varying amounts of water decreases with increasing water content (Table 20). The detonation becomes unstable if the sample contains more than 36 mass-% water.

Table 20: Detonation velocity of aqueous hydrazinium(1+) nitrate solutions.

Data source: [119]

1.6.4 Explosive Yield of Hydrazinium Nitrate

In the lead block test, the cavity volume increase by detonation of solid HN is 408 cm³/10 g. For hydrazine/HN solutions, the explosive yield as measured by the increase of cavity volumes in lead blocks depends on the mixture ratio of hydrazinium(1+) nitrate (HN) oxidizer and hydrazine fuel. Maximum Trauzl block indentations were obtained with N₂H₄—N₂H₅NO₃ mixtures away from the stoichiometric composition [125]. The cavity volume increased from 370 to a maximum of 430 cm³ by increasing the HN content from 40 to 60%. Beyond 60% HN, the lead block cavity

volume dropped back to 340 cm³ at 100% HN. Similar mixtures with hydrazinium(1+) perchlorate achieved higher maximum indentations, 470 cm³ instead of 430 cm³.

The explosive force can be measured not only by lead block indentation, but also in a ballistic mortar and expressed as TNT equivalency. In this test 1,1-dimethylhydrazinium nitrate, methylhydrazinium nitrate, and HN measured 106, 136, and 142% equivalent to TNT in a ballistic mortar [13, 14]. These nitrates are thus more powerful explosives than TNT. Accidental accumulation of these nitrates in combustion residues in small rocket engines, in particular following short pulse widths, and subsequent explosion can cause substantial damage to the hardware.

1.6.5 Explosive Applications of Hydrazinium Nitrate

There are hundreds of patents describing the use of HN in explosives, along with a long litany of other ingredients. Most of these patents are for water-based, slurry, and gelled explosives and most of them also include AN or methylammonium nitrate as an ingredient. The reason for adding HN to AN slurries is to increase their cap sensitivity and detonation velocity. Only a few examples of explosives with HN are included here because some of them have compositions similar to those of HN-based monopropellants. HN-based monopropellants are described in *Encyclopedia of Monopropellants*.

In a few instances it was a misbehaving HN-based rocket propellant that was then claimed as a new powerful explosive and developed into a commercial product.

1.6.5.1 Explosives Based on Hydrazinium Nitrate

Owing to its high shock and friction sensitivity, HN cannot be safely used as an explosive for military applications or commercial excavations in the solid state. All detonation experiments with pure HN were done strictly to satisfy academic interest. That has not prevented investigators from looking at HN mixtures and HN solutions for commercial and military applications.

Slabs of cast and solidified HN (180 × 120 × 12 mm) did not detonate stably and required the addition of more than 20% PETN or 30% 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX) to achieve a stable detonation at this thin diameter [130]. Melt-processed mixtures of HN with PETN, HMX, or RDX had higher explosive performance as measured by C-J pressure, detonation velocity, and Gurney energy than the pure materials by themselves. Based on tests with twelve different blends, a 30 HN/70 HMX mix had the highest Gurney energy and a 45 HN/55 HMX mix had the highest detonation velocity (9.030 km/s) [131]. X-ray flash photography was used to observe the progression of the detonation front into the sample. HN should not be mixed with nitroguanidine, as it begins an exothermic reaction with ammonia evolution.

Fused mixtures of AN with 5–50% HN have improved detonation properties over those of AN by itself [112]. The explosives may contain 0.5% Al, 3% carbon, and 7.5% TNT as fuels. Detonation velocity and card gap sensitivity increase with increasing HN content of the mixtures.

Some transition metal nitrate/HN double salts or complex salts containing hydrazinium ion or free hydrazine in the ligand sphere can be used as primary explosives [132]. Metal hydrazine nitrate complexes tested for that purpose included $[\text{Ni}(\text{N}_2\text{H}_4)_3](\text{NO}_3)_2$ [133], $[\text{Zn}(\text{N}_2\text{H}_4)_2(\text{NO}_3)_2]_n$, $[\text{Cd}(\text{N}_2\text{H}_4)_2(\text{NO}_3)_2]_n$, and $[\text{Co}(\text{N}_2\text{H}_4)_3(\text{NO}_3)_2]$ [134]. The thermal behavior, kinetics, thermal safety, and storage life of these salts were investigated by DSC, thermogravimetric analysis (TGA), and dynamic pressure measuring thermal analysis methods.

1.6.5.2 Liquid Explosives Based on Hydrazinium Nitrate

A product line of hydrazine-based two-component explosives has been developed by the former Explosives Corporation of America (Excoa) and was at one time marketed under the name “Astrolite®.” The advantage was that the two components could be shipped (or even air-freighted) separately under a less restrictive shipping designation and mixed only at the point of end-use. The mixtures contained 70–92% oxidizer (HN or HN/HP mixture 4:1) including up to 25% of alkali metal nitrates, calcium, or aluminum nitrates or perchlorates, 6–15% hydrazine, and 2–15% ammonia [135]. The mixtures could be made starting with hydrazinium salts and adding ammonia gas, but it was more practical to start with hydrazine and ammonium salts. The ammonia liberated by the reaction of hydrazine with ammonium salts remained in the solution. A sample containing 79% HN, 7% hydrazine, and 14% ammonia had a detonation velocity of 8100 m/s and a freezing point of 251 K (–8 °F). Other cap-sensitive two-component explosives can be prepared *in situ* from AN instead of HN and hydrazine-water mixtures [136]. One such mixture consisted of 60% AN, 30% AP, 15% hydrazine, and 5% water, and had a detonation velocity of 3300 m/s. Later modifications of this explosive composition included aluminum powder and a gelling agent [137]. Example compositions of these heavily aluminized hydrazine explosives consisted of 2–45% Al, 0–18% NH_3 or NH_4^+ , 6–75% N_2H_4 or N_2H_5^+ , and 15–70% NO_3^- ion. Guartec or fumed silica was used as a gelling agent to keep the metal particles in suspension. Typical examples were 19% hydrazine, 48% AN, and 33% aluminum, or 10% hydrazine, 57% HN, and 33% aluminum.

The two-component field mix capability of Astrolite explosives makes these explosives practical for applications where large quantities of live explosive cannot be stored near the application site or where transportation restrictions do not allow the shipping of live explosives (e.g., as air freight). For convenience, the AN can be prepackaged in plastic bottles accompanied by a separate, leak-proof container for hydrazine. Immediately prior to use, the metal can with hydrazine inside a flexible plastic bottle is opened by squeezing a lever and allowed to mix with the AN (Safe-T-Pack). A typical composition was 53.0% AN and 13.2% AP in the solid and 26.4% hydrazine, 4.1% AN, and 3.3% H_2O in the liquid phase [138]. Another mixture consisted of a solid component containing 89.9% AN, 10% AP, and 0.1% inerts and the liquid component consisted of 43.48% hydrazine, 25.22% water, 18.26% methanol, and 13.04% AN [139].

Astrolite-type two-component explosives were tested for oil and gas well stimulation under a series of US Bureau of Mines and US Department of Energy contracts to Petroleum Technology Corporation [140]. The process was called Astro-Frac®.

In testing Astrolite-G (the exact composition is proprietary), it was concluded that the liquid explosive can be initiated with an M6 blasting cap, has the same relative sensitivity to friction or impact as solid secondary high explosives, and is stable at 278–538 K [141]. The drop-weight sensitivity on the Olin drop-weight tester with a 2-kg weight was 27.5 cm, similar to that of unsensitized nitromethane (28.6 cm) but much less sensitive than *n*-propyl nitrate (15.5 cm). In the rifle bullet (0.30 caliber from 90 ft) impact test, the material would detonate when contained in metal containers but would not detonate in polyethylene or rubber bags. Some tests were conducted with the dry crystals (most likely HN) for sensitivity to electrostatic discharge and friction. The crystals withstood 11 J, an electric discharge well above the level of discharge likely to be carried by a person. The dry crystals did not detonate when tested on the Picatinny Arsenal Abrasive Tab Friction Pendulum Apparatus. In the card gap test, liquid Astrolite-G was positive at 20 cards. The addition of 20% water lowered the sensitivity to positive at 12 cards and 32% water lowered it to positive at zero cards. The frozen undiluted explosive had a sensitivity of five cards; it was less sensitive than the liquid. All positive tests went high order, as evidenced by the hole sheared from the witness plate. The detonation velocity of the unboosted (cap initiation only) explosive in stainless steel pipes measuring 25 mm (1 in) in internal diameter (I.D.) with a wall thickness of 1.65 mm (0.065-in) was 8400 m/s. Tests in polyethylene plastic tubes gave similar results. The addition of 22% water lowered the detonation velocity to 7600 m/s.

Solutions of HN in hydrazine hydrate (HH) become detonable once the HN concentration exceeds 40 to 45% [40]. Detonability in this case was determined with the sample contained in a brass tube measuring 20 mm in I.D., 120 mm long with 1-mm walls, and initiated by a 10-g tetryl booster. In a wedge test, the critical thickness was measured for HN concentrations of 45, 55, and 65% and decreased from 5 to 1.3 to 0.6 mm. The low critical thickness of a fraction of a millimeter for the highest HN concentration mix is particularly remarkable, considering that many commercial explosives have critical diameters in the order of several centimeters. The detonation velocity of a blend consisting of 68 HN/29.1 HH/2.9 H₂O ($\rho = 1.3416 \text{ g cm}^{-3}$) as a function of temperature was measured over the range 283–333 K and can be expressed by the equation

$$D = 8.13 - 0.0032(T - 273)$$

where D is the detonation velocity in km/s and T is the temperature in kelvin. It is interesting to observe that the decrease in density due to thermal expansion has a dominating effect on detonation velocity, in spite of the higher energy content of a warmed explosive. The detonation velocity (extrapolated to an infinite diameter) at a constant temperature (293 K) varied linearly with the HN concentration from

7.793 km/s for 55% HN to 8.492 km/s for 80% HN. At concentrations above 70% HN in a sample 20 mm in diameter, the explosive exhibited LVD as well as HVD, but the critical diameter for LVD was much higher than that for HVD.

It was found that HN-based liquid mixtures explode upon coming in contact with alkali metals and their alloys [142]. This method of initiation is suitable for explosive drilling in deep bore holes.

An HN/HH explosive with a density of 1.31 g cm^{-3} had a measured detonation velocity of 7.246 km/s and its lead cylinder compression value was larger than 35.3 mm [143].

Molten HN in a steel tube is very shock sensitive. A sample tube filled with 300 g of molten HN dropped on a steel plate from a height of only 50 cm exploded on impact [130]. HN is more sensitive in the molten state than in the solid state. With TNT, the relationship is the other way around.

Another explosive containing HN is Hydan-II, a mixture of HH and AN developed at Dynamit Nobel Wien in 1994 [144]. It has a detonation velocity of 7150 m/s.

Instead of mixing HN with hydrazine (hydrate), liquid or slurry explosives can also be obtained by mixing HN with organic aliphatic amines [145, 146]. One example is a composition containing 80 mass-% HN, 15% monoethanolamine, and 5% water, which had a density of 1.42 g/cm^3 and a detonation velocity of 7.81 km/s. Explosion did not occur even after dropping a 5-kg weight on the explosive from a height of 60 cm.

1.7 Applications of Hydrazinium Nitrate in Liquid Rocket Propellants

There are many liquid monopropellant blends containing HN and their physical and safety properties should have been reported at this location. However, in a few instances we have discussed these propellants where they were formulated and tested as monopropellants such as in *Encyclopedia of Monopropellants*. The same applies to solid propellants containing HN, which are to be discussed in later volumes planned in this series.

2 Hydrazinium Perchlorates

Hydrazine forms two types of perchlorates when reacted with perchloric acid or other perchlorates, depending on the ratio of reactants, hydrazinium(1+) perchlorate (HP1) or hydrazinium(2+) perchlorate (HP2). A very good summary of properties of hydrazinium perchlorates and other perchlorates is provided in publications by Pearson [147, 148]. Hydrazinium(1+) perchlorate and hydrazinium(2+) (di)perchlorate are both very explosive substances that explode readily when overheated rapidly or subjected to mechanic or electrostatic stimuli [149].

A detailed summary of the properties of hydrazinium(1+) perchlorate and hydrazinium(2+) perchlorate was already published in the author's earlier books on hydrazine [2], pages 120 through 272, and [3], pages 220 through 375. Additional information on hydrazinium perchlorates is contained in the book by Patil and Rattan [4], pages 70 through 74. The main emphasis in the current chapter is on publications that have appeared in the interim or that were not already included in the two earlier books.

2.1 Hydrazinium(1+) Perchlorate

Hydrazinium(1+) perchlorate, also known as hydrazinium monoperchlorate, hydrazine monoperchlorate, HP, HP1, HP-1, CAS RN [27978-54-7], or CAS RN [13762-80-6], is a very sensitive oxidizer and cannot be safely used in the pure state. Hydrazinium(1+) perchlorate is also called hydrazine **monoperchlorate** or hydrazinium **monoperchlorate** in order to differentiate it from hydrazinium **diperchlorate**.

2.1.1 Production of Hydrazinium(1+) Perchlorate

Hydrazinium(1+) perchlorate is easy to prepare by direct neutralization of hydrazine hydrate in dilute solution with diluted perchloric acid under stirring and with adequate cooling. It has been known for a very long time, but has not yet found a practical use [150].

Hydrazinium(1+) perchlorate can be prepared by **slowly** neutralizing 60% HClO_4 with 75% $\text{N}_2\text{H}_5\text{OH}$ at temperatures from 273 to 298 K (0 to 25 °C). The salt precipitates as the hemihydrate from water at 273 K (0 °C) and is filtered cold in sintered glass funnels (avoid the use of filter paper!). The fine white crystals are gently removed from the filter with a Teflon spatula and placed in a drying tube at 343 K (70 °C) for 2 h at a constant vacuum of 0.05 mm Hg to dehydrate the hemihydrate [151]. Only very few hydrazinium salts crystallize with water of hydration, and hydrazinium(1+) perchlorate is one of them.

When preparing hydrazinium perchlorates, one must be careful to use perchloric acid or perchlorates that do not contain any chlorate ion. Hydrazinium chlorate is the most sensitive contaminant in this category and traces of it may alter the behavior of either HP1 or HP2.

Hydrazinium(1+) perchlorate can be prepared by the reaction of barium perchlorate with hydrazinium hydrogen sulfate in aqueous solution. It is easy to filter off the insoluble barium sulfate and concentrate the filtrate (with precautions from behind a barrier).

Hydrazinium(1+) perchlorate can be made by metathetical reaction of hydrazine and AP in aqueous solution

where the equilibrium is shifted to the right by driving off the ammonia [152]. In one example, 0.17 mol of anhydrous hydrazine (AH) was added to a solution of 0.17 mol of AP in 4.4 mol of water at 300 K (27 °C). The mixture was heated with stirring to 373 K (100 °C) for 5 h to drive off most of the ammonia, followed by heating to a higher temperature to drive off 3.3 mol of water and the rest of the ammonia. On cooling the mixture to 278 K (5 °C), the hemihydrate precipitated in the form of white crystals. The hemihydrate can be dehydrated by heating in anhydrous isopropanol. It is unclear why this cannot be made starting with hydrazine hydrate instead of the more expensive AH.

The direct dehydration of HP hemihydrate to the anhydrous salt at 333 K (60.5 °C) was a generally accepted fact for several decades. However, sporadic reports had indicated the possible existence of other hydrates in the $\text{N}_2\text{H}_5\text{ClO}_4/\text{H}_2\text{O}$ system. Detailed reexamination of the phase diagram of this system did not reveal any additional compounds other than the hemihydrate at 19 mass-% H_2O [153]. The melting point curve showed a discontinuity at 19% H_2O , 337 K, indicating the occurrence of a hydrate that decomposes at this temperature. The continuous uninflected line disproved any other hydrates postulated in the previous literature. A eutectic point occurred at 80 mass-% H_2O and 269 K. The melting point of pure crystalline HP was fixed at 415.5 K (142.4 °C). Vapor pressure curves obtained for different salt-hydrate compositions between 278 and 349 K showed that dehydration occurs at 337 K, and the heat of vaporization of water from the hemihydrate was 73.6 kJ/mol (17.6 kcal/mol) at 293 K.

A continuous production process for prilled anhydrous HP1 starts with a simple neutralization reaction between hydrazine (hydrate?) and perchloric acid and the aqueous solution is dehydrated in a flow-through falling film evaporator at or below atmospheric pressure, where all water is evaporated and the HP emerges as an anhydrous melt at 418–423 K (145–150 °C), then sprayed on a spinning plate where it is spun out by centrifugal forces into a cooling tower in which it consolidates to spherical particles [154].

Hydrazinium(1+) perchlorate can be prepared by reaction of barium perchlorate with hydrazinium(1+) chloride in ethanol or isopropanol [155]. Eutectic mixtures of HP1 with lithium perchlorate can be used as oxidizers in rocket propellants and have reduced sensitivity to impact (see Section 2.1.5.1).

2.1.2 Physical Properties of Hydrazinium(1+) Perchlorate

The physical properties of HP1 and its hemihydrate are summarized in Table 21 and in Table 22.

Table 21: Physical properties of hydrazinium(1+) perchlorate $\text{N}_2\text{H}_5\text{ClO}_4$.

2.1.2.1 Solubility of HP1 in Water

A study of phase equilibria in the system hydrazine perchlorate/water showed that a solid hydrate was formed, decomposing at 337 K (64 °C) and the phase diagram has

a eutectic point at 269.05 K (-4.1°C) and 80% water [153]. The melting temperature of the anhydrous salt was at 415.5 K (142.4°C). A further determination was made of vapor pressures of water vapor in equilibrium with the condensed phases from 278 to 348.7 K (5.0 to 75.6°C). These experiments identified the hydrate as $\text{NH}_4\text{ClO}_4 \bullet \frac{1}{2}\text{H}_2\text{O}$, and fixed the quadruple point at 337 K (64°C) and 88 mm Hg. The solubility of HP1 in water or ethanol is summarized in Table 23. The solubility data are useful in preparing HP1 and HP1 hemihydrate.

Table 23: Solubility of hydrazinium(1+) perchlorate in water or ethanol.

2.1.2.2 IR Spectra of Hydrazinium(1+) Perchlorate

When it was attempted to record the IR spectrum of HP1 hemihydrate by the pressed KBr pellet method, the measured spectrum corresponded to that of a mixture of potassium perchlorate and hydrazinium bromide, the result of an unwanted metathetical reaction in the presence of water (hydrate water) [156]. Subsequently, three spectra of HP1 hemihydrate in different organic solvents with different peak-free ranges were spliced together.

IR spectra of hydrazinium(1+) perchlorate hemihydrate and the anhydrous salt (both in Nujol mulls and pressed in KBr pellets) were recorded and compared to understand the forces that hold the hydrates in the crystals [163]. The possibility of the proton being shared between the hydrazinium cation and water present as the oxonium ion, H_3O^+ , has been investigated. Absorption frequencies of N_2H_5^+ are observed at 3400 – 3300 , 1570 , and 960 cm^{-1} and those of perchlorate at 1100 and 620 cm^{-1} . It is interesting to note additional bands at 3280 , 2560 , 2000 , and 1570 cm^{-1} , which could be due to oxonium (H_3O^+) ions or H-bonded water as normal H_2O of hydration does not exhibit such absorptions, and only OH protons could be seen. The IR spectra of $\text{N}_2\text{H}_5\text{ClO}_4 \bullet \frac{1}{2}\text{H}_2\text{O}$ and the anhydrous salt in Nujol mull are shown in Figure 15.

Figure 15: Infrared spectra of (a) $N_2H_5ClO_4 \cdot \frac{1}{2}H_2O$ and (b) the anhydrous salt. (Republished and modified from [163], with permission of © 1983 Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

2.1.2.3 Molecular Structure of Hydrazinium(1+) Perchlorate

HP1 crystallizes in monoclinic crystals, space group $C2/c$ with a density of 1.939 g/cm^3 at 288 K. Crystals of hydrazinium(1+) perchlorate and hydrazinium(1+) tetrafluoroborate are isostructural: both are monoclinic, space group $C2/c$, with eight formula units per unit cell [67]. The crystal parameters of HP were already summarized in Table 14.

2.1.2.4 Thermodynamic Properties of Hydrazinium(1+) Perchlorate

Thermodynamic properties of HP were already summarized in Table 21 and additional data are provided in Table 26. The heat of formation of a mixture of AP and HP was determined by calorimetry to be -210.4 kcal/mol .

2.1.3 Chemical Properties of Hydrazinium(1+) Perchlorate

2.1.3.1 Reactions of Hydrazinium(1+) Perchlorate

Hydrazinium perchlorates form ammoniates when the anhydrous salts are saturated with anhydrous gaseous ammonia under pressure [161]. If one attempts this reaction with aqueous ammonia instead of anhydrous ammonia, one only obtains a mixture of salts. Hydrazinium perchlorate ammoniate, $N_2H_5ClO_4 \cdot NH_3$, is non-hygroscopic and can be stored without decomposition. In the IR spectrum one can observe bands at 1400 and 750 cm^{-1} , which are characteristic of coordinated ammonia. In the DTA, hydrazinium(1+) perchlorate ammoniate has a melting endotherm at 410 K (137°C) and

a decomposition exotherm at 513 K (240 °C). A similar diammoniate has been prepared from hydrazinium(2+) perchlorate, which melts at 373 K (100 °C) and decomposes at 491 K (218 °C).

2.1.3.2 Thermal Stability of Hydrazinium(1+) Perchlorate

When dry samples of hydrazinium(1+) perchlorate or hydrazinium(2+) diperchlorate were decomposed slowly in a stream of carbon dioxide, the diperchlorate produced some hydrogen azide, but the monopерchlorate did not [164]. Both liberated nitrogen, oxygen, chlorine, chloride, and ammonium. In the case of hydrazinium(1+) perchlorate, the decomposition reaction and its kinetics can be studied only when the substance is heated slowly.

Anhydrous HP1 begins to decompose at temperatures close to its melting point [157]. The weight loss of HP begins between 433 and 523 K. After a 6-min heating period, the following weight losses were observed on 0.2-g samples: not measurable at 433 K, 0.3% at 453 K, 0.7% at 473 K, 3.1% at 493 K, and 5.4% at 513 K. Above 523 K (250 °C) the salt decomposed rapidly and rapid combustion of HP occurred at 523 K. When heated at a rate of 20 °C/min, HP1 in a bath of Woods metal heated at a rate of 20°/min starting at 373 K autoignited at 553 K (280 °C) compared with 633 K (360 °C) for AP. The addition of 5% MnO₂ or Cu₂Cl₂ lowered the autoignition temperature to 527 K (254 °C) and 443 K (170 °C) respectively.

Decomposition products of HP1 are ammonium perchlorate, hydrazinium chloride, water, nitrogen, and a small amount of chlorine [165]. The activation energy is about 83.7 ± 1.2 kJ/mol (20 ± 0.3 kcal/mol).

The thermal decomposition of HP1 was studied between 403 and 473 K (130 and 200 °C) [151, 166, 167]. No decomposition was detected at 403 K (130 °C) for over 100 h. Decomposition between 413 and 473 K (140 and 200 °C) followed a power law relationship during an induction period and a linear law from 10 to 80% completion of reaction. The activation energy of the rate-determining step was 99.6 kJ/mol (23.8 kcal/mol), quite close to that obtained for anhydrous perchloric acid. See also [168].

When heated under the necessary precautions, HP1 can be sublimed nearly undecomposed [109, 158, 160]. The heat of sublimation was derived from the slope of the vaporization rate curve and was found to be 124 kJ/mol (29.6 kcal/mol), essentially identical to that of AP. Attempts to sublime HP2 resulted in partial decomposition and the sublimate was essentially pure HP1.

The overall stoichiometry of HP decomposition can be described by

The rate of decomposition accelerated for $0 < \alpha < 0.1$ and remained constant during $0.1 < \alpha < 0.7$. The activation energy during the mid-phase of the reaction sequence was

about 99.6 kJ/mol (23.8 kcal/mol) [169, 170]. One of the several mechanisms proposed starts out with a proton transfer

followed by decomposition of the perchloric acid to form chloryl radicals, which can react with more HP1 (or with N_2H_4):

where it was assumed that the perchloric acid pyrolysis is the rate-controlling step.

Hydrazinium(1+) perchlorate exists in the anhydrous form and in the form of a hemihydrate. The hemihydrate loses water and is dehydrated to the anhydrous salt if heated at 333.6 K (60.5°C) under vacuum. Decomposition studies under vacuum starting with the hemihydrate should be identical to those of the anhydrous salt if the sample is kept near this temperature long enough before increasing the temperature any further.

Table 24 is a summary of the endotherms and exotherms observed during the DTA and DSC thermal analysis of various hydrazinium perchlorates and their hydrates and ammoniates.

Key: + endotherm, – exotherm, m = melting point (melting endotherm)

The thermal decomposition of HP1 in the solid state leads to ammonium perchlorate, hydrogen chloride, nitrogen, and water:

The activation energy for this reaction, as gauged by the rate of HCl evolution measured in a mass spectrometer, is 33.7 kJ/mol (8.05 kcal/mol) between 353 and 393 K

[171]. At 393 K, the weight loss stabilizes at 29% only after 5 days of heating. Doping the HP1 with perchlorates of ammonium, aluminum, or calcium at 1 mol% had no pronounced effect on the rate of decomposition. Higher additive concentrations should have been studied to obtain a noticeable stabilizing or catalyzing effect.

The kinetics of the thermal decomposition of molten HP1 were measured in the temperature range from 418 to 468 K in a constant-volume vacuum line that was initially evacuated to 1.32×10^{-4} Pa (10^{-6} mm Hg) [172]. A liquid nitrogen trap was attached to the system so that all condensables would be immediately removed. The rate of pressure buildup from non-condensable gases was measured with a McLeod gauge. The composition of the gases could also be measured in situ through a side tap connected to the inlet of a mass spectrometer. In addition, TGA and DTA data were taken on other samples. Based on those data, a slightly different equation for the decomposition of HP1 was then proposed:

The formation of H_2 and N_2O had not yet been observed by previous investigators.

Analysis of decomposition rate data at different temperatures gave an activation energy of 150 kJ/mol (35.9 kcal/mol). When HP1 was doped with inert diluents (NH_4^+ , Ca^{2+} , Al^{3+} , SO_4^{2-}), a systematic decrease in the reactivity of HP1 was observed. Therefore, it seems possible that the rate-determining step is the formation or dissociation of an associated complex involving $\text{N}_2\text{H}_5\text{ClO}_4$.

The vaporization and sublimation products of HP, as studied by a cold matrix isolation technique and identification of products by IR absorption spectra are hydrazine and perchloric acid [173]. Other IR bands found in the products were assigned to NH_3 , HCl , and H_2O . At higher temperatures (436–483 K = 163–210 °C) the intensity of NH_3 and H_2O IR bands (but not those of HCl) increased more rapidly than those of N_2H_4 or HClO_4 . Comparing the vaporization temperatures of HP, AP, hydroxylammonium perchlorate (HAP), and methylammonium perchlorate, the relative vaporization temperatures could be correlated with the pK values of the bases in aqueous solution.

The rate of decomposition of dehydrated HP1 and HP2 between 413 and 473 K in a glass-walled constant-volume reactor was measured by recording the decomposition pressure [170]. Decomposition products were analyzed (gases by MS and condensed products by conventional wet methods). The composition of the products indicated the following reaction:

During the initial phase the reaction was self-accelerating, but the rate remained constant between 10 and 70% of complete decomposition. The activation energy in the temperature range of this study was 100 kJ/mol (23.8 kcal/mol). Like other investigators before and after them, Grelecki and Cruice assumed that the initial step in the thermolysis of HP1 is the dissociation into hydrazine and free perchloric acid. Because

the activation energies of HP1 and HClO_4 decomposition are very similar, HClO_4 decomposition is likely to be the rate-controlling step in HP1 decomposition. Addition of acids accelerates HP decomposition. The decomposition of HP is a matter of HClO_4 decomposition, whereas the rate of HN decomposition is determined by the rate of hydrazine decomposing. Some of the HClO_4 decomposition occurs as a heterogeneous reaction on the wall of the vessel [174].

Hydrazinium(1+) perchlorate hemihydrate decomposes in two stages [15]. First, it melts and undergoes dehydration, showing a broad endotherm. The thermal decomposition of hydrazinium(1+) perchlorate hemihydrate slows down with progressive decomposition, and the kinetics did not conform to any of the usual rate equations like those used for AP. The decomposition was studied in a constant volume bomb with condensation of the products in an LN2 trap and also by TGA at atmospheric pressure between 453 and 502 K [175]. The following overall reaction represents approximately the product composition formed:

This may be the result of the following intermediate reaction steps in the temperature range 423–523 K (150–250 °C):

The activation energy of the decomposition reaction between 453 and 553 K was 152.7 kJ/mol (36.5 kcal/mol) based on pressure rise measurements and 179.8 kJ/mol (35.8 kcal/mol) based on weight loss rate measurement. The fact that the volatile products were condensed as soon as formed and thus removed from further reaction may account for the difference between this equation and the one shown earlier. In addition, this experiment was extended to 553 K, where NH_4ClO_4 begins to decompose.

Hydrazinium(1+) perchlorate ammoniate $\text{N}_2\text{H}_5\text{ClO}_4 \bullet \text{NH}_3$ and hydrazinium(2+) perchlorate diammoniate $\text{N}_2\text{H}_6(\text{ClO}_4)_2 \bullet 2\text{NH}_3$ were prepared by reaction of the corresponding hydrates with ammonia gas [161]. The thermal properties of the ammoniates are quite different from those of the corresponding hydrates. In the case of hydrazinium(2+) perchlorate, the ammoniate decomposes at temperatures 50 K below those of the hydrate. If the DTA of hydrates is carried out under vacuum, several steps can be identified that belong to the dehydrated salts as intermediates.

2.1.4 Strand Burning of Hydrazinium(1+) Perchlorate

Strand-burning studies of HP were plagued by the unreproducible burning behavior of some of the samples [157]. Initially, it was not possible to ignite HP packed into glass tubes measuring 1.05 cm in I.D. with an electrically heated wire at atmospheric pressure. The salt melted, ignited briefly, and extinguished after a layer of 1–2 mm was consumed. Rapid combustion occurred only if HP was preheated to 523 K. HP/AP mixtures containing 30–60% HP burned stably at 0.13 to 0.22 cm/s. The rate of HP decomposition was accelerated significantly by adding 5% manganese(IV) oxide, cobalt(II) oxide or copper(I) chloride as combustion catalysts. The linear burning rates of these catalyzed mixtures were much faster than those of the corresponding AP mixtures. The addition of 5% MnO_2 , CoO , or Cu_2Cl_2 as combustion catalysts enabled the strand burning of HP powder at ambient pressure. Observed burning rates were 0.13, 1.0, and 1.6 cm/s, for the three additives respectively. A mixture of AP with 30 to 60% of HP without catalytic additives burned steadily at 0.13 to 0.22 cm/s in a tube 1.05 cm in (inside) diameter at room temperature and at 1 atm.

Smooth deflagration was achieved sporadically for both tamped ($\rho = 1.1\text{--}1.3\text{ g/cm}^3$) and pressed HP pellets ($\rho = 1.8\text{--}1.9\text{ g/cm}^3$) at 24.2 to 434 kPa (0.24 to 4.3 atm), with and without preheating [109]. Later experiments with HP from a different source did not reproduce these results. HP mixed and pressed with a solid fuel (polyacetal) burned in a stable and reproducible manner. Paraformaldehyde and s-trioxane were not suitable for these tests because they reacted prematurely with HP. For stable combustion of pressed HP, a minimum addition of 5% copper chromite or potassium dichromate was required, whereas magnesium oxide was a more effective catalyst and steady burning stabilization was achieved with only 2% of the additive. The upper limit for stable combustion of HP/fuel propellants is 778 kPa (7.7 atm). At times, smooth deflagration was obtained at 202-, 404-, or 606-kPa pressure, but this could not be repeated in later tests. A tamped sample ($d = 1.1\text{ g/mL}$) containing 5% CuCrO_2 burned at a rate of 1.2 cm/s. A similar sample pressed to a density of 1.93 g/mL burned slower, at 0.7 cm/s. Magnesium oxide was less effective than CuCrO_2 as a catalyst. Similar burning rate studies were conducted for HP2 (see Section 2.2.4).

2.1.5 Safety Properties of Hydrazinium(1+) Perchlorate

2.1.5.1 Drop Weight Impact Sensitivity of Hydrazinium(1+) Perchlorate

Hydrazinium(1+) perchlorate has an impact sensitivity of $0.2\text{ kpm} = 2\text{ Nm}$. Other investigators reported that it was giving 88% detonations under a 5-kg weight dropped from a height of 15 cm [157].

The drop weight sensitivity of HP1 is dependent on the amount of water in the sphere of hydration [152]. As shown in Figure 16, the drop height required to achieve a 50% probability of ignition of a 20-mg sample with a 2-kg weight goes through a maximum (least sensitive) at a composition that would correspond to

Figure 16: Drop weight impact sensitivity of hydrazinium(1+) perchlorate with varying water content. (Reproduced and modified from [152].)

a monohydrate $\text{N}_2\text{H}_5\text{ClO}_4 \cdot \text{H}_2\text{O}$, but HP1 typically crystallizes as a hemihydrate, not a monohydrate.

Hydrazinium(1+) perchlorate forms two eutectics with lithium perchlorate, one with a 1:1 molar ratio and another one with a 1:2 molar ratio, that have substantially lower impact sensitivity than HP1 itself. The 50% probability of ignition when impacted with a 2-kg weight is 51.2 cm for the 1:2 eutectic and 26.3 cm for the 1:1 eutectic, which is substantially less sensitive than the dry HP1 alone (6 cm) [155, 176, 177].

2.1.5.2 Friction Sensitivity of Hydrazinium(1+) Perchlorate

Although all other tests indicated that HP is very sensitive, the friction sensitivity was reported as only 1 kp = 10 N pistil load with no reaction

2.1.6 Explosive Performance of Hydrazinium(1+) Perchlorate

2.1.6.1 Explosive Yield of Hydrazinium(1+) Perchlorate

In duplicate tests in different sized lead blocks with 10-g samples of dry crystalline HP, lead block indentations of 383 and 388 cm³ were reported [157]. For comparison, triaminoguanidinium nitrate has a Trauzl volume of 350 cm³. The corresponding triaminoguanidinium perchlorate has a Trauzl volume of 465 cm³ and is a more energetic explosive.

The book by Meyer on explosives cites a lead block volume of 362 cm³/10 g. The critical diameter in the steel sleeve test was 20 mm [144].

The explosive force can be measured not only by lead block indentation but also in a ballistic mortar and expressed as TNT equivalency.

Hydrazinium perchlorate contaminated with hydrazinium chlorate is a dangerous product. Hydrazinium(1+) chlorate is less stable than HP or HN and extremely friction

sensitive. In the Trauzl block its indentation was 278% that of mercury fulminate and 100% that of TNT. In the same test, HP gave a lead block indentation of 113% of that of picric acid and 122% of that of TNT [178].

2.2 Hydrazinium(2+) Perchlorate

Hydrazinium(2+) perchlorate, $\text{N}_2\text{H}_6(\text{ClO}_4)_2$, HP-2, HP2, hydrazinium(2+) diperchlorate, hydrazine diperchlorate, CAS RN [13812-39-0] is a very intriguing oxidizer and in spite of many attempts, it was not possible to incorporate it into a stable and storable propellant. Some researchers also refer to the hydrazinium(2+) salts as hydrazonium salts, but that is not correct.

2.2.1 Production of Hydrazinium(2+) Perchlorate

Hydrazinium(2+) perchlorate has been known for a very long time, but it has yet to find a practical application [179]. When reacting hydrazine hydrate with an excess of perchloric acid, the HP2 salt is first obtained in the form of its dihydrate, $\text{N}_2\text{H}_6(\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}$. HP2 can be obtained by reaction of 85% $\text{N}_2\text{H}_5\text{OH}$ and 72% HClO_4 under the necessary precautions (active stirring in an ice bath) to prevent overheating. Although dry HP2 is less sensitive than HP1, the dehydration of the dihydrate can be a dangerous operation and must be conducted at temperatures at or below 353 K (80 °C) under vacuum. The dihydrate salt can also be dehydrated by digestion with excess 70% HClO_4 at room temperature, filtering off the solid, and vacuum drying at a somewhat elevated temperature [180].

Dry anhydrous HP2 is extremely hygroscopic. Powdered HP2 in air at 50% relative humidity (R.H.) absorbs 0.065 mol of water per mol of HP2 within only 40 min [181].

It is very difficult to prepare pure HP2. Common contaminants are HP1 and perchloric acid. Potential contaminants are chlorate and chloride ion. These contaminants may have a strong effect on the thermal stability of HP2.

Anhydrous HP2 can be prepared by reaction of hydrazinium(2+) chloride powder with 72% perchloric acid under heating, which drives off the HCl [182, 183]. After the evolution of HCl has diminished, the mixture is evacuated under stirring to below 1 mm Hg pressure and sparged with nitrogen gas to remove residual HCl. After 4 h the resulting slurry is filtered, giving a filter cake of nearly anhydrous HP2.

Anhydrous hydrazinium(2+) diperchlorate can be made by reacting a hydrazinium(2+) dihalide and a perchlorate of sodium, potassium, ammonium, cesium, or rubidium with hydrogen fluoride under anhydrous conditions [184, 185]. The reaction may take place in an inert atmosphere at a temperature of 283–333 K (10–60 °C). The insoluble product may be separated by decantation or filtration and washed with anhydrous hydrogen fluoride. Residual hydrogen fluoride is removed by subjecting the product to a high vacuum at a temperature above 323 K (50 °C). The

product is free from hydrazinium monoperchlorate and may be used as an oxidizer in propellant compositions.

A process that avoids the use of perchloric acid in the synthesis of HP2 starts out with a suspension of NaClO_4 in aqueous hydrochloric acid and then under stirring, adding hydrazinium(1+) or hydrazinium(2+) chloride with continued stirring [186]. Then, the slurry is heated under stirring to 323–333 K (50–60 °C) until the sodium chloride precipitates. The hot filtrate is cooled to 298 K (25 °C) where the HP2 hydrate crystallizes out. The HP2 hydrate can then be dehydrated by known methods.

Anhydrous hydrazinium(2+) perchlorate, substantially free from hydrazinium(1+) perchlorate, can be made by reacting one molar part of hydrazine with more than two molar parts of perchloric acid, the reaction mixture containing less than 30% by weight of water [187]. Liquid or aqueous hydrazine may be added to a concentrated solution of perchloric acid, and the reaction mixture cooled or evaporated to crystallize out the product. Alternatively, hydrazine vapor in an inert carrier gas can be passed into a concentrated solution of perchloric acid. The reaction product is filtered off and the liquid phase can be recycled after concentration by evaporation.

Hydrazinium(2+) perchlorate forms a double salt $(\text{NH}_4)_2\text{N}_2\text{H}_6(\text{ClO}_4)_4$ with ammonium perchlorate, which is substantially more stable than HP2 itself [188, 189]. The double salt has a higher specific impulse than AP and is less hygroscopic than hydrazinium(2+) perchlorate. It is also compatible with the commonly used organic polymer fuel-binders. The crystal density is 2.08 g/cm³. The impact sensitivity of the double salt H_{50} was 40 cm (16 in), much less sensitive than HP2.

2.2.2 Physical Properties of Hydrazinium(2+) Perchlorate

The physical properties of HP2 are summarized in Table 25.

Table 25: Physical properties of hydrazinium(2+) perchlorate and hydrazinium(2+) dperchlorate dihydrate.

2.2.2.1 Molecular Structure of Hydrazinium(2+) Perchlorate

The hydrazinium(2+) perchlorate dihydrate crystallizes in monoclinic crystals that melt at 368 K (95 °C). The IR spectrum of $\text{NH}_4(\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}$ in a KBr pellet is shown in Figure 17.

2.2.2.2 Thermodynamic Properties of Hydrazinium(2+) Perchlorate

The heat of formation of $\text{N}_2\text{H}_6(\text{ClO}_4)_2$ has been determined from the heat released during the reaction [191]:

A summary of thermodynamic data of hydrazinium perchlorates is provided in Table 26.

A double salt of AP and HP2 called DAHTP from Thiokol Chemical Corporation was found to be a 2 : 1 mixture of NH_4ClO_4 and $\text{N}_2\text{H}_6(\text{ClO}_4)_2$. Heat of solution measurements yielded a heat of formation of -880 kJ/mol (-210.4 kcal/mol) [194].

2.2.3 Chemical Properties of Hydrazinium(2+) Perchlorate

2.2.3.1 Reactions of Hydrazinium(2+) Perchlorate

Studies of the stability of HP2 and HAP and their compatibility with binders and curing agents showed that HP2 was more reactive than HAP or AP [195]. Binders investigated included hydroxy- and carboxy-terminated polybutadiene and polyisobutylene prepolymers, and poly-1,2-bis(difluoramino)-2,3-propylene oxide. Binder prepolymers studied were hydroxyl terminated polyisobutylene (UTREZ-diol), carboxyl terminated UTREZ, hydroxyl terminated polybutadiene (R-45-M), carboxyl

terminated polybutadiene (Telagen CT), saturated hydroxyl terminated Telagen, a carboxyl terminated polyisobutylene (EMD-590), and two ethyl acrylate-acrylic acid copolymers. The curing agents studied included four isocyanates, an aziridine curing agent, and an epoxide (ERLA-4221). Studies with AP were included to provide a baseline for comparing the relative merits of the two more energetic oxidizers. Later in the program, and after HP-2 was essentially eliminated as a candidate oxidizer, compatibility of HAP with two NF plasticizers, 1,2,3-tris[1,2-bis(difluoramino)]ethoxy propane and 2,3-bis(difluoramino)-propyl-2,2-dinitropropylcarbonate (P-722) and with aluminum hydride (LMH-I) were studied. At the time this program was initiated, nitronium perchlorate was being eliminated as a candidate advanced oxidizer, HAP and HP-2 were still considered to be attractive oxidizers. During 1967, it became increasingly apparent that HP-2 afforded little prospect of being used in an advanced propellant system, particularly in conjunction with NF binders, plasticizers, and the advanced fuels. HAP, which was slightly more attractive from a compatibility viewpoint than HP-2, was carried along as a candidate advanced oxidizer.

Researchers at the Midwest Research Institute have screened-the reactivity of HP-2 with various structural functionalities found in solid propellant systems [196]. Their approach consisted of measuring the rates as well as determining the nature of oxidizer-substrate reactions and oxidizer decomposition over a range of temperatures, usually 298, 313, 333, and 353 K (25, 40, 60, and 80 °C). They found that HP-2 acted as an oxidizing agent toward organic substrates, although the reaction became apparent and significant only over a relatively long period of time, usually 2 months.

This oxidative behavior of HP-2 becomes important when the long-range aging behavior of propellants formulated with HP-2 is considered. Carbon dioxide evolution from hydrocarbon materials indicated ~1% reaction (on a mole basis) after approximately 2 months. Of special significance, the urethane cure linkage in the binder suffered degradation (through what appears to be decarboxylation) when contacted with HP-2 at room temperatures [197].

2.2.3.2 Thermal Stability of Hydrazinium(2+) Perchlorate

Hydrazinium(2+) perchlorate is an acid-base salt consisting of a stable perchlorate salt (HP) to which a second perchloric acid moiety is loosely bonded. The decomposition of HP-2 is a two-stage reaction in which the first step is the “easy” loss of the loosely held acid moiety to give HP and anhydrous perchloric acid. The rate of the reaction is controlled by perchloric acid decomposition in the second step.

The thermal decomposition of HP2 *in vacuo* is preceded by an extended induction period during which there was only a gradual pressure increase [170]. At the end of the induction period the reaction accelerated sharply and led to complete decomposition within a few hours. However, this phenomenon was not confirmed by later investigators.

Grelecki and Cruice have reported that after dissociation occurs to the monoperchlorate and free per-chloric acid, the latter decomposes as it is considerably less stable than either HP or HP-2. Grelecki and Cruice, utilizing a manometric technique, have reported a value of 98.3 kJ/mol (23.5 kcal/mol) as the activation energy for HP-2 decomposition between 1273 and 1773 K (1000 and 1500 °C).

Hammond et al. [198] have calculated a similar value of 96.2 kJ/mol (23 kcal/mol) for the HP-2 decomposition process from mass spectral data.

Fast vacuum pyrolysis techniques were combined with a Bendix Time-of-Flight mass spectrometer for the study of the initial reactions occurring during thermal decomposition of HP2 [199]. Primary decomposition mechanisms were postulated, and activation energies calculated. The total ion current trace of the mass spectrometer as a function of sample temperature with a linear heating rate showed two peaks. The initial peak is most likely caused by the loss of one HClO_4 moiety, leaving hydrazinium(1+) perchlorate (HP1). The HP1 then vaporizes at the higher temperature, and yields its characteristic mass spectral cracking pattern. For hydrazinium(2+) perchlorate (HP2), the activation energy values were 96 kJ/mol (23 kcal/mol) for the initiating reaction by the mass spectral thermal analysis method compared with 98 kJ/mol (23.5 kcal/mol) obtained by Grelecki and Cruice, using time-to-acceleration of heated samples contained in scaled, evacuated bulbs.

The close similarity of the activation energies for HP-2 decomposition and that for perchloric acid indicate the rate-controlling step to be the decomposition of the free acid.

Analysis of the gaseous decomposition products by MS and analysis of the condensable products by wet chemistry confirmed the following stoichiometry for the decomposition of HP2:

For HP2, there was a very sharp transition at the initiation of the accelerated phase, for example, after 75 h at 413 K. An activation energy of 98.3 kJ/mol (23.5 kcal/mol) was derived from the temperature dependence of the induction period.

Analysis of gaseous and condensed products of HP2 decomposition in the range from 447 to 566 K (174 to 293 °C) indicates a more complicated stoichiometry [109, 158, 160, 181, 200]:

Addition of 1% of perchloric acid dihydrate to fresh HP2 doubled the reaction rate. As perchloric acid is one of the decomposition products of HP2, it is most likely responsible for the autocatalysis observed during HP2 decomposition. Addition of anhydrous perchloric acid instead of the dihydrate accelerated the rate of decomposition at 393 K to a point where it was so fast that it resulted in a runaway situation. The rate under this condition was at least 60 times faster than the normal rate of decomposition. Small amounts of ammonia extended the induction period (a similar effect is observed when adding ammonia to AP).

The effect of dopants, aging, particle size, and pre-irradiation on the thermal decomposition of HP2 has been investigated. All hydrazinium salts are very sensitive to contaminant or non-stoichiometric lattice defects that may lower the threshold temperature of autodecomposition. In the case of hydrazinium(2+) perchlorate, anion vacancies produced a sensitizing effect, whereas cation vacancies had a stabilizing effect [201, 202]. The decomposition of HP2 may involve the migration of ionic species and electron transfer from ClO_4^- to $\text{N}_2\text{H}_6^{2+}$. Data on the uptake of $\text{N}_2\text{H}_6\text{SO}_4$ indicate that these impurities are distributed homogeneously in the HP2 crystal lattice. The rate of decomposition was found to decrease with age. The aging effect was attributed to a decrease in anion vacancy concentration with age. Particle size did not seem to have any effect on the decomposition of HP2. Pre-irradiation was found to affect the decomposition appreciably only when the samples were irradiated for longer durations (1 h), the effect being observed only during the later stages of the decomposition ($\alpha > 0.3$).

The efficiency of sensitizing additives to HP1 and HP2 decreased in the order $\text{CuCrO}_4 > \text{CuCl}_2 > \text{NiO} > \text{Fe}_2\text{O}_3 > \text{MgO}$ [203]. The activation energy was determined by measuring the delay time to explosion when rapidly heating the sample. The impact sensitivity of some of the sensitized samples was similar to that of mercury fulminate, a primary explosive. The temperatures of explosion (for a 5-s delay) as extrapolated from the plot of explosion delay time versus temperature were 541 and 547 K (268

and 274 °C) respectively for HP and HP2. The optimal amount of additive to achieve the most pronounced lowering of the activation energy (calculated from the change in ignition delay time) was between 2 and 4 mass-%. For example, a maximum of sensitizing of HP2 was observed with 4 mass-% of CuCrO_4 when the temperature of explosion decreased from 551 K (278 °C) (for pure HP2) to 513 K (240 °C) and the activation energy value decreased from 91.2 kJ/mol (21.8 kcal/mol) (for pure HP2) to 49.4 kJ/mol (11.8 kcal/mol).

The kinetics of HP2 thermal decomposition were studied by flash mass thermal analysis [198]. In this method, microgram-sized specimens were mounted on a platinum ribbon and inserted into the ionization chamber of a time-of-flight mass spectrometer. Extremely rapid heating rates (up to 3×10^7 K/s) were possible with this arrangement. The decomposition mechanism derived from the mass spectrometer data agreed well with mechanisms proposed by previous investigators [170].

The activation energies for the thermal decomposition of HP1 and HP2 are very similar and both are similar to the activation energy for the decomposition of pure perchloric acid. Therefore, it has been suggested that the rate-determining step in either decomposition reaction is the decomposition of perchloric acid.

The mechanism for the decomposition of HP2 is assumed to be very similar to that of the decomposition of HP1 discussed above:

followed by decomposition of the perchloric acid to form chloryl radicals that can react with more HP (or with N_2H_4):

Hydrazoic acid has been noted among the decomposition products from HP-2.

2.2.4 Strand Burning of Hydrazinium(2+) Perchlorate

Pressed pellets of HP2 burn with a non-luminous flame [109, 158, 160]. During the burn, a melt layer forms on the surface, the thickness of which is pressure dependent and decreases with increasing pressure. There is foaming and bubbling in the liquid layer, best observed at low pressures and less pronounced or invisible at high pressures. If combustion was quenched, the melt layer could be sampled and analyzed. It was shown to contain considerable concentrations of AP. The lowest pressure at which strands could be burned reproducibly was 606 kPa (6 atm). Burning at 101 kPa (1 atm) was not always possible. Extrapolating from data obtained at pressures above 101 kPa, the burning rate at 101 kPa would be 0.002 cm/s.

The deflagration rate of pressed cylinders of HP2 (8 mm diameter by 20 mm length, pressed density 2.11 g/cm^3) after ignition with a glow wire was measured at 0.6–35 MPa nitrogen pressure [181]. The strand burning rate dependence on pressure shows two distinctly different slopes, indicating different mechanisms below and above 10 MPa. Below 10 MPa, the burning rate increases from 0.02 to 1 cm/s, and above 10 MPa, it increases to 1.4 cm/s:

$$\text{Below 10 MPa} \quad r = 1.75 \times 10^{-3} p^{1.44}$$

$$\text{Above 10 MPa} \quad r = 0.28 p^{0.28}$$

where r is the burning rate in cm/s and p is the pressure in atm. At high pressures the flame is stabilized above the oxidizer. Heat from this exothermic reaction zone is radiated back to the condensed phase, causing gasification. At pressures below 2 MPa, the oxidizer is mainly consumed by a rapid, self-sustaining decomposition. At the highest pressures tested, the measured flame temperature approached the theoretical temperature (1604 K). One percent copper chromite increased the burning rate from 0.002 to 0.081 cm/s; 5% increased it to 0.25 cm/s. Sodium nitrosopentacyanoferrate(III) or magnesium oxide were less effective burning rate catalysts.

The flame temperature of hydrazine diperchlorate deflagration was measured using fine wire Chromel Alumel thermocouples [158, 204]. At 28 atm the measured temperature was found to be 200 °C below the calculated product gas temperature. The observed temperature increased with pressure, and at approximately 100 atm the theoretical value was attained. A study of the thermal behavior of hydrazine and perchloric acid was extended to include a review of reactions of chlorine oxides, intermediates in the decomposition of HP1 and HP2 [205].

2.2.5 Safety Properties of Hydrazinium(2+) Perchlorate

2.2.5.1 Drop Weight Impact Sensitivity of Hydrazinium(2+) Perchlorate

The drop-weight impact sensitivity of HP2 was determined in a drop weight sensitivity test apparatus with a 2.26-kg (5-lb) weight by the Bruceton up-and-down method. The drop weight impact sensitivity was compared to that of other energetic materials. The 50% point of HP2, HMX, AP, or dextrinated lead azide was 0.53, 0.58, 1.17, and 0.63 m respectively [180]. The “wet cake,” an interim product consisting of HP2 wet with HClO_4 , was slightly more sensitive (0.43 m) than the dry salt.

2.2.5.2 Shock Sensitivity of Hydrazinium(2+) Perchlorate

Hazard property tests conducted on HP2 before scaling up a process for pilot quantity production indicated that the dry salt is very sensitive in comparison to HMX, AP, or even lead azide [180]. A 60% slurry in water was given an explosive Class B transportation classification, but the dry salt was classified as a Class A Type 4 explosive. Desensitizing additives, such as tricalcium phosphate, were considered to improve the handling and transportation safety of the material. See also [206].

2.2.5.3 Friction Sensitivity of Hydrazinium(2+) Perchlorate

Solid and dry hydrazinium salts may be quite friction sensitive. Friction sensitivity of dry HP2 was surpassed only by that of lead azide, 10.9 kg_f compared with 0.9 kg_f [180]. By comparison, friction sensitivity of HMX and AP in the same apparatus was 15 and 31 kg_f respectively; HP2 wet with HClO₄ tested at 15.9 kg_f.

Hydrazinium(1+) perchlorate is more sensitive to friction than HP2 but both are comparatively less sensitive to friction than mercury fulminate or lead azide [206]. Sensitivity to impact was higher for HP2 than for HP. The friction sensitivities were appreciably increased in the presence of metal oxide additives and the sensitizing efficiency followed the same relative order as impact sensitivity.

2.2.5.4 Electrostatic Sensitivity of Hydrazinium(2+) Perchlorate

Electrostatic discharge sensitivity of dry HP2 powder was intermediate between that of HMX and AP. The dry powder ignited at 0.5 J, whereas HMX ignited at 0.1 J and AP ignited at 1.6 J [180]. Surprisingly, “wet cake,” a mix of HP2 and HClO₄ obtained during the production of HP2, was more sensitive than dry HP2 (0.2 compared with 0.5 J).

2.2.6 Explosive Performance of Hydrazinium(2+) Perchlorate

The detonation velocity of dry HP2 is 4700 m/s [180]. The critical diameter in unconfined samples is 8 mm; in confined samples it is as low as 1.3 mm.

2.2.7 Applications of Hydrazinium Perchlorates

Hydrazinium perchlorates 1 and 2 have been used as the oxidizer in solid propellant formulation studies in combination with various polymeric binder systems.

3 Hydrazinium Nitroformate

Hydrazinium nitroformate, also known as HNF, CH₅N₅O₆, hydrazinium trinitromethide, hydrazinium trinitromethanide, hydrazine trinitromethanide, hydrazine nitroformate, CAS RN [20773-28-8]; also CAS RN [17181-40-7], is a promising oxidizer for solid propellants and liquid monopropellants.

Salts of nitroform (trinitromethane) are sometimes also called trinitromethides or trinitromethanides.

Ammonium dinitramide and hydrazinium nitroformate (HNF) are two new halogen-free oxidizers that compete for applications both in solid propellants and in monopropellants. It depends on which application one has in mind before one can decide which of the two makes a better rocket propellant. Neither contains chlorine, so there would be no hydrogen chloride in the exhaust. Several publications have presented a comparison of the two “green” oxidizers. In looking for environmentally more friendly oxidizers for solid propellants, ADN

and HNF are emerging as likely substitutes for AP. Although both ADN and HNF have lower oxygen balance (+25 and +13% respectively), their enthalpy of formation ΔH_f (−167 and −71 kJ/mol = −40 and −17 kcal/mol respectively) is superior to that of AP. For solid propellants, ADN has the advantage of higher oxygen content, but the disadvantage of hygroscopicity and worse sensitivity [207]. For its intended use as an oxidizer in solid propellants, HNF has several advantages over ADN such as higher melting point, better thermal stability [208, 209], less troublesome hygroscopicity, and ease of synthesis in a single-step reaction. Besides applications in solid propellants, both HNF and ADN have promising properties as green liquid monopropellants when dissolved in water or methanol.

Hydrazinium nitroformate is one of the most powerful solid oxidizers available, but it has poor compatibility with commonly used hydroxy-terminated polybutadiene (HTPB) binders, which is attributed to oxidation of the double bond (C=C) in HTPB by the HNF. In order to characterize HNF, many thermoanalytical techniques, such as DSC and TGA/DTA, have been used to obtain more information about its stability and its compatibility or incompatibility with other materials. When the oxidation of HTPB occurs, it results in deterioration of the binder, which leads to unacceptably low mechanical properties. Isocyanates also show poor compatibility with HNF. Glycidyl azide polymers (GAPs) do not contain carbon-carbon double bonds, may be safely used with HNF, and could offer higher performance than the existing AP/Al/HTPB propellant formulations. The exhaust gases from an HNF/GAP propellant system are halogen free and environmentally more friendly than AP exhaust. The purity of HNF is important as unreacted nitroform or hydrazine gets absorbed in the HNF crystals, posing safety and stability problems during later handling and storage. HNF-based propellants possess high burn rates (30 mm/s at 5.5 MPa) and a high pressure exponent ($n = 0.81 - 0.83$). The pressure exponent can be reduced to 0.59 with suitable burn-rate modifiers. It was estimated that by using HNF-based propellants, an increase in I_{sp} of more than 7% and a payload gain of 10% may be possible.

Additional HNF information is in the author's hydrazine books at pages 90 (preparation), 122 (melting point), 173 (density), 220 (heat of formation), 401 (decomposition), 816 (solid propellant oxidizer) of the first edition [2] and again on pages 118–119 (preparation), 164 (melting point), 231 (density), 291 (heat of formation), 558 (decomposition), 1543–1546 (solid propellant oxidizer) of the second edition [3] of this comprehensive review of hydrazine chemicals.

Several retrospective surveys of the history of the development of HNF as a rocket propellant have been published, including Schöyer et al. [210]. Although HNF was first prepared in 1951 and a major production effort was initiated in the US, research and development was stopped in 1975 because HNF caused unwanted interactions with most solid propellant binders available at that time. HNF was “rediscovered” in 1987 by Nederlandse Organisatie Voor Toegepast-Natuurwetenschappelijk Onderzoek (TNO) Prins Maurits Laboratorium in The Netherlands under a program funded by the

European Space Agency and the Netherlands Agency for Aerospace Programs. The main interest in HNF was centered in Europe, with TNO Prins Maurits Laboratorium (a government entity) and Aerospace Propulsion Products (private industry) cooperatively taking the lead in The Netherlands. Other countries with active HNF research programs included India [211], China [212, 213], and Japan [214].

3.1 Preparation of Hydrazinium Nitroformate

Although the production of HNF is based on a simple acid-base reaction, the quality of the resulting product strongly depends on the preparation and crystallization techniques used. For a propellant oxidizer, control of particle size and size distribution in the production phase of the crystals is important. The effect of different crystallization processes on product quality is very pronounced. Stability depends, among other factors, on purity and/or contamination. Production of HNF is a two-step procedure: The preparation of trinitromethane (nitroform, NF) and the neutralization and salt formation with hydrazine (hydrate). The trinitromethane needed as a starting reactant for HNF production can be obtained by nitration of isopropanol with white fuming nitric acid (see *Encyclopedia of Oxidizers*, chapter “Nitromethanes”). The difficult part is the separation of NF from the excess nitric acid because NF and nitric acid form an azeotrope.

The steps in manufacturing of HNF are as follows: the $\text{H}_2\text{O}/\text{NF}$ mixture is separated by the addition of salt. Nitroform is extracted with dichloroethane (DCE) and separated from the salt solution. Anhydrous hydrazine or hydrazine hydrate is added under controlled conditions to the NF/DCE mixture and HNF precipitates. The remaining steps of the production process are performed to improve the quality and purity of the HNF.

The production of HNF used high-purity grade AH as a starting ingredient. High-purity grade AH has a purity of better than 99.25% and does not contain aniline, but is rather expensive. Experiments showed that using commercial hydrazine hydrate also led to a good-quality HNF product. The costs of hydrazine hydrate are much lower than those of AH. Substantial cost savings are possible and an additional advantage is the reduced hazard level when working with hydrazine hydrate instead of AH. Results of gas evolution during Vacuum Thermal Stability (VTS) tests for hydrazine hydrate-based HNF were superior to AH-based HNF (especially at $353\text{ K} = 80^\circ\text{C}$). The melting temperatures also improved whereas the pH remained within the correct range.

Hydrazinium nitroformate is not compatible with an excess of hydrazine. Excess hydrazine must be avoided when making HNF. Some patents suggest the use of excess nitroform in order to avoid excess hydrazine. The melting temperature T_m of HNF was highest ($387.8\text{ K} = 114.7^\circ\text{C}$) when HNF was produced with minimal excess hydrazine and worst ($385\text{ K} = 111.9^\circ\text{C}$) when HNF was produced with large excess hydrazine. At the same time the VTS values ($333\text{ K} = 60^\circ\text{C}$, 48 h) were 0.67 and 3.59 mL/g respectively.

Constantly measuring the pH during the addition of hydrazine (hydrate) to the NF/DCE mixture and halting the addition of hydrazine at a more acidic point increased the yield from 83 to 87%, and VTS data also improved.

By using hydrazine hydrate instead of AH and recovering methylene chloride and methanol solvents, the cost of HNF production can be substantially reduced and no negative effects on HNF quality were detected after making these process changes. The quality and production yield of HNF were improved by reducing excess amounts of hydrazine hydrate and filtering and washing of raw HNF on the same day it was produced [213].

Hydrazinium nitroformate can be prepared by adding hydrazine dropwise to a solution of trinitromethane in 2-propanol until the precipitation is complete [215, 216]. The heat of neutralization released during this reaction is 84 kJ/mol. The precipitate is washed, recrystallized from 2-propanol, and dried. The salt melts at 394–397 K (121–123 °C) and is stable for 18 months at 373 K. The yield of HNF achieved by this method is only 50%. Another method is described in US Pat. No. 3378594 [217], where equimolar amounts of hydrazine (hydrated or non-hydrated) are mixed with nitroform at 273 to 323 K and atmospheric pressure. Water can be present as a solvent in large amounts or the reaction is carried out in the presence of an organic solvent such as methanol. It appears from US Pat. No. 3378595 that the stability of HNF depends on the ratio of the hydrazine to the nitroform and on the purity of nitroform and solvent.

Most HNF is prepared starting with hydrazine hydrate, which is less costly than AH. It was claimed that it is possible to obtain HNF with a very high purity and yield, starting from high-purity-grade AH. Improved yield and HNF properties are said to be achieved by carrying out the reaction in a liquid/liquid two-phase system [218, 219]. According to these patents, HNF is prepared by dissolving nitroform of a purity of better than 98.5 mass-% in a medium that is a solvent for the nitroform, but is a non-solvent for the HNF to be formed, and then reacting the dissolved nitroform with a stoichiometric amount of hydrazine with a purity of better than 99.0 mass-% while stirring in the presence of a small amount of proton-transferring medium. Both solutions are chilled to 273–278 K prior to mixing and temperature is maintained below 278 K. The proton-transferring medium can be water and/or a lower (C_1 – C_6) alcohol such as methanol or 2-propanol. The solvent for nitroform can be dichloroethane (preferred) or dichloromethane (second-choice alternative). This method enables the production of hydrazine nitroform of such a high purity that it was no longer necessary to use any stabilizer at all, because the lack of stability was found to be caused by the presence of impurities. For reasons of safety, the nitroform is mostly shipped as an aqueous solution containing 32% nitroform. Nitroform can be used by extracting it from the aqueous solution by means of dichloroethane. The nitroform can also be isolated by salting it out from the solution by means of NaCl, KCl, or NaNO₃. NaCl is the most economical choice. In salting out at temperatures just barely above the melting point of nitroform (295 K), a two-phase system is formed, comprising a water layer and

a liquid nitroform layer. The nitroform layer is separated from the brine layer and the residual water/brine is also removed from the nitroform layer to ensure that neither salts nor other impurities present in the water will be carried over into the end product. The presence of chloride ions (inclusions of brine in the HNF layer) can give rise to a reduction of the stability. After all hydrazine has been added, stirring is continued for 60 min at a temperature of approximately 273 K in an ice bath. After stirring, the crude HNF is removed from the reactor, the supernatant liquid is decanted, and the wet product is dried. Optionally, the crude product thus obtained can be purified by means of recrystallization in 2-propanol.

For several years Aerospace Propulsion Products B.V. (APP) in The Netherlands produced HNF in its pilot plant facility. The development of HNF and HNF-based propellants was performed in cooperation with European Space Agency (ESA), TNO (NL), Nobel Energetics (UK), and Avio (Italy), amongst others. APP was the sole commercial producer of HNF world-wide. It was hoped that some of the properties of HNF could be improved by co-crystallization with other oxidizers. The APP production facility, built in 1993, allowed for the simple acid-base reaction that constituted the fundamental step in HNF manufacturing. Reactions took place in a large stirred and temperature-controlled reactor vessel. As of 2002, it allowed for the production of 3–5 kg HNF per batch and had a maximum capacity of ~300 kg HNF per year. All commercially available European HNF during 1993–2008 was produced in this facility. New methods to improve the thermal stability and to control the crystal size were identified and have been implemented in the production process at APP. Work was done on (co)crystallizing HNF with other ingredients such as stabilizers, and the compatibility and thermal decomposition of HNF were investigated. See also [220].

A new method [221] for the preparation of trinitromethane by nitration-hydrolysis of 4,6-dihydroxypyrimidine (DHP) promises to lead to better yields and improved purity of HNF, although the starting materials are more expensive than isopropanol or acetylene [222]. DHP can be prepared via cyclocondensation of dimethylmalonate with formamide as raw materials. NF is then obtained via a nitration-hydrolysis reaction of DHP. The results showed that for up to 80.1% NF yield, the optimal reaction conditions were: the molar ratio of nitric acid to DHP of 5:1, the mol ratio of sulfuric acid to nitric acid of 3.5:1.0, reaction temperature of 318 K (45 °C), and reaction time of 2 h. There is a safe method of isolating NF and converting it to HNF. HNF with a purity of 98.9% was obtained using NF that was prepared under the optimized conditions as a starting material. See also [223].

Nitroform can be prepared by nitration of isopropanol. The mechanism of the nitration reaction was discussed and the optimal reaction conditions of preparing NF were determined as a function of the ratio of (fuming HNO_3):(*i* – PrOH) = 12:1, reaction temperature of 333 K = 60 °C, and reaction time of 3 h [224]. The yield of NF was 46.6%, 21.6% higher than reported in the literature. HNF with a purity of 99.7% was synthesized by the reaction of hydrazine hydrate and nitroform and its structure was characterized by single crystal XRD structure analysis, IR, ^1H NMR, ^{13}C NMR, and MS.

The results showed that the crystal is monoclinic, space group $P2_1/n$. In the crystal lattice, the nitroformate anions and hydrazinium cations connect via hydrogen bonds, and each unit cell contains two independent HNF molecules.

Nitroform can be made by adding a solution of isopropanol in ethylene dichloride (EDC) drop-wise to a nitrating mixture of fuming nitric acid and concentrated sulfuric acid in EDC at 313–333 K (40–60 °C), neutralizing with solid sodium bicarbonate in EDC, followed by extraction with water. HNF is then made by reacting nitroform with a solution of hydrazine hydrate, drying at 323–343 K (50–70 °C), purifying HNF by dissolving in a solvent, filtering and drying the precipitated HNF followed by coating HNF crystals with a surfactant by dissolving HNF in an alcohol/ketone solution containing a surfactant [225].

The influence of various factors such as reaction temperature, time, and amount of anhydrous HNO_3 on yield of nitroform, as well as the effect of temperature on the extraction efficiency, was examined and NF was obtained with an optimal yield of 53.6%, which was far beyond that reported up to that time in the literature (25%) [226]. The synthesis of HNF was achieved by the neutralization reaction of NF with equal molar hydrazine hydrate (80%) instead of AH. The crystal morphology of HNF was adjusted through varied crystallization methods such as anti-solvent crystallization, sono-crystallization, and sequential cooling crystallization in order to decrease the sensitivity. HNF crystals obtained from sequential cooling crystallization displayed excellent morphology with a length/diameter ratio (L/D) close to 1:1. Sensitivity performance toward external stimuli, especially friction and electrostatic discharge, was improved greatly in comparison with that of crude HNF without the crystallization process.

3.1.1 Recrystallization Methods

There were three different recrystallization processes in use during the development of HNF: cooling crystallization (**C**), the solvent/non-solvent process (**S**), and evaporative crystallization (**E**). These lead to crystals with somewhat different characteristics, including size and aspect ratio (L/D), but also different stability characteristics in VTS tests. The HNF that is produced after the addition of hydrazine to the nitroform/dichloroethane mixture must meet certain requirements. In the past, a recrystallization step was necessary to improve purity, thermal stability, and morphology. Now the goal is to produce HNF crystals with the desired shape and purity in one process without recrystallization [227].

During the **C** process, a solution of HNF in methanol is cooled below the saturation point. Seed crystals can be used to induce the nucleation process. The L/D can thus be controlled by adjusting the rate of cooling.

During the **S** process, an HNF solution in methanol is added to a non-solvent, methylene chloride. The methanol dissolves in methylene chloride, causing the HNF

to precipitate. This results in fairly small HNF crystals. Size and L/D of the crystals can be controlled during this process.

During the **E** process, HNF is dissolved in isopropyl alcohol. This solution is subsequently heated, and IPA is vaporized under vacuum while HNF crystallizes. This leads to a better HNF purity, but to a non-controlled morphology and mean crystal size.

Crystallization during ultrasonic agitation (20 kHz) can change the crystal properties. Ultrasonic agitation in combination with the **C** process gave excellent improvements in crystal morphology, a reduction in the particle size, and improvement in the bulk (tap) density. The L/D improved from 4–8 by going to 2.6–3.3. Even the thermal stability of HNF crystals improved (lower gas evolution in VTS). In itself, there is no major objection to a somewhat wider particle size distribution because a high solids load in a solid propellant requires multimodal particle size distribution.

Another method of crystal shape modification is cocrystallization. Cocrystallizing may be done for a number of reasons, including:

- 1) to include a ballistic modifier (e.g., a burning rate modifier) in the oxidizer,
- 2) to include a stabilizer in the oxidizer,
- 3) to coat the crystals with a protective layer, or
- 4) to make a premix of HNF and the binder.

The shape and particle size of HNF crystals can be controlled by recrystallization from a solution of 16–20 mass-% HNF in acetonitrile as a solvent, introducing a predetermined volume of a non-solvent and then cooling the mixed solution of HNF in acetonitrile and the non-solvent [228].

3.1.2 Crystal Shape Modification Methods

A substantial amount of effort has been devoted to the morphology of HNF crystals and new methods for obtaining HNF with different, more processable crystal shapes to start with or to re-crystallize the needle-shaped intermediate product to obtain more spherical particles with a smaller L/D ratio, such as those shown in Figure 19. Ultrasound can be used to induce nucleation at lower supersaturation levels [229]. The application of ultrasound during cooling recrystallization of HNF was already shown to have a positive influence on morphology (aspect ratio and particle size) on a small scale. Scaling up of this production technique to pilot-scale showed that the trend toward morphology and stability improvement can be preserved. The preferred frequency for sonocrystallization is 20 kHz and the amplitude is up to 20 μm . The ultrasound treatment was tested for drowning-out crystallization or cooling crystallization (with and without the addition of seed crystals) and showed improvement in crystal shape for cooling crystallization, but adverse changes for drowning-out crystallization. The stability of HNF was characterized by vacuum stability tests and by headspace gas chromatography-mass spectrometry (GC-MS).

The patents [230, 231] claim a wider range of conditions, e.g., ultrasound with frequency 10–100 kHz and amplitudes of 0.4–10 μ . The same method can be applied to recrystallization of other energetic materials such as CL-20, ADN, AP, RDX, HMX, and PETN.

Another crystallization process applied to recrystallization of HNF is the proprietary ICI process, which results in powders that have more desirable shapes of crystal morphology. HNF from the ICI process had aspect ratios near 1 and only the larger particles (10–90 μ m) had a tendency to form needles. Unfortunately, smaller particles gave a lower onset of exotherm in the DSC and had a higher rate of gas evolution in the VTS. The head space above HNF samples during vacuum stability tests at 313 to 353 K was analyzed by GC-MS and provided additional information beyond that obtained from a traditional VTS. For instance, N_2O could be detected in the headspace after 400 h at 313 K = 40 °C, 200 h at 333 K = 60 °C, and 70 h at 343 K = 70 °C. At 353 K = 80 °C the rate of gas evolution (all gases, with N_2O as the major product) was very rapid and the test had to be terminated after 95 h.

It is common practice to redissolve HNF and recrystallize it, but most recrystallized HNF crystals are still needle-shaped with an L/D of 4 to 5, which makes it difficult to process them into solid propellants. Instead of dissolving and recrystallizing the elongated crystals, it has also been proposed to compress them under a pressure of at most 7 MPa (preferably between 4 and 5.75 MPa) to a semi-solid cake and then reclassify the broken material to form a material having the desired L/D ratio ($L/D < 2.5$) [232]. This patent has been filed in many foreign countries in addition to the Dutch [233], US, European [234], and World [235] filings, including Canada [236], Norway [237], Germany [238], Austria [239], and Australia [240].

Various methods were tried out during HNF crystallization to obtain improved crystal shapes, which include mechanical stirring, ultrasound agitation, and using crystal shape modifiers (CSMs). Experimental results showed that a multi-pronged approach to controlling the shape and size of the crystals by a careful choice of CSMs and crystallization method worked best to counter the preferential axial crystals growth, thus shifting the shape of long needles to near cubical shape [241].

Crystal shapes of many solid propellant oxidizers need to be changed to decrease sensitivity, improve mechanical properties and to get optimal performance from oxidizers such as ADN or HNF [242].

3.1.3 Morphology of HNF Crystals and Methods for Recrystallization

In the as-produced state, HNF often forms long needles (Figure 18) with L/D ratios of up to 8 which do not have a suitable optimal shape for incorporation into solid propellants [210].

Figure 18: Hydrazinium nitroformate crystallized by slow cooling of a solution, high length/diameter ratio, 1994 technology. (From [210])

If the hot HNF solution is allowed to cool with ultrasonic agitation, the crystals assume a more rounded shape with smaller L/D ratios (Figure 19).

Figure 19: Hydrazinium nitroformate crystallized with ultrasonic agitation, low length/diameter ratio, 1999 technology. (From [210])

A very useful chapter on the crystallization of chemicals with special reference to HNF is contained in [243]. It includes nicely illustrated information on the best crystallization methods for HNF using different solvents and cooling rates.

3.1.4 Coating of HNF Crystals

It has been attempted to reduce the reactivity of HNF with solid propellant binders and to reduce its friction sensitivity by coating with inert polymers that could at the same time aid as bonding agents. Among various coating agents, an HTPB-based clay nanocomposite was found to be most effective for reducing the friction and impact sensitivity of HNF [241]. Using a technique similar to one previously used on wax-coated RDX, the extent of coating on HNF was analyzed by SEM-EDAX so as to achieve a correlation between coating thickness and improved insensitivity. The coating material was thermally stable and compatible with the HNF crystals as revealed by thermal analysis.

It was attempted to prevent incompatibility reactions between HNF and solid propellant polymeric binders by encapsulating the oxidizer particles in a compatible polymer coating.

3.2 Physical Properties of Hydrazinium Nitroformate

The physical properties of HNF are summarized in Section 3.2.1 to 3.2.9. See also [244]. The molecular mass of HNF is 183.081 g/mol.

3.2.1 Melting Point of Hydrazinium(1+) Nitroformate

The melting point of early samples of HNF was reported to be 396.9–397.5 K = 123.8–124.4 °C, but samples of higher purity analyzed in 2000 showed an onset of melting in the DSC at 403.9 to 404.1 K (130.8 to 131.0 °C) [245]. These samples started to decompose at 407.4 K (134.3 °C). Other samples of recrystallized HNF in MeOH/carbon tetrachloride yielded yellow needle-shaped crystals with a melting point of 393 K (120 °C). Inferior grades of HNF may melt at 388 K (115 °C).

3.2.2 Density of Hydrazinium(1+) Nitroformate

The density of two batches of solid HNF was determined using two different methods [245]. The results are the average of duplicate tests and are compared in Table 27. The difference between the density of the two batches is relatively large. It was suggested that batch E8 might be more porous than batch C9.

Because the natural crystal shape of HNF is in the form of long needles that do not pack very well and which are difficult to process into solid propellants, the bulk density (“tap density”) of HNF is sometimes taken as an evaluation criterion for its suitability for solid propellants. If the bulk density of the as-produced HNF is too low, the material may have to be recrystallized.

Table 27: Density of hydrazinium(1+) nitroformate.

3.2.3 Vapor Pressure of Hydrazinium(1+) Nitroformate

The temperature dependence of molten HNF vapor pressure above the burning surface of HNF in the temperature interval from 550 to 750 K can be calculated from [249]

$$\ln P = 17.03 - \frac{9909}{T}$$

where P is the pressure in atm and T is the temperature in kelvin. The slope of this curve corresponds to a heat of evaporation (or sublimation) of 164.8 kJ/mol.

3.2.4 Solubility and Hygroscopicity of HNF

To measure the hygroscopic point, a saturated solution of HNF was placed in a desiccator equipped with a hygrometer [245]. The relative humidity above the saturated solution was 94%. HNF is less hygroscopic than AN, which becomes deliquescent at 62% R.H. No moisture uptake could be measured with samples kept at 20% or 65% R.H. HNF starts taking up moisture only if the surrounding relative humidity is $\geq 94\%$.

The solubility of N₂H₅C(NO₂)₃ (HNF) in water at 293 K (20 °C) is 52.88 mass-% HNF [58]. The solubility of HNF in water is approximately 50% at 293 K (20 °C) and 80% at 328 K (55 °C).

3.2.5 Optical Properties of Hydrazinium(1+) Nitroformate

3.2.5.1 UV-Visible Absorption Spectra

The UV spectra of HNF solutions in water have maxima of absorption at 210 and 352 nm [250] (Figure 20). Because hydrazine by itself has an absorption peak at 210 nm and

Figure 20: Ultraviolet-visible absorption spectra for hydrazine (bottom), nitroform (middle) and HNF (top) dissolved in water. (Reproduced from [250]; with permission granted by Dr. Jeroen Louwers, 27 May 2020)

nitroform by itself has absorption peaks in that area, it appears that the peaks of HNF are a composite (additive behavior) of its two parent molecules.

The relative peak heights ($\lambda_{\max}$ 210 nm vs 352 nm) of a UV spectrum shown by Dendage, Asthana, and Singh [251] were very similar, whereas the 352-nm peak in Figure 20 above is much smaller. Other sources [252] report a $\lambda_{\max}$ at 348 nm and $\epsilon = 1.5 \times 10^{-4} \text{ L mol}^{-1} \text{ cm}^{-1}$.

The absorption peak at 350 nm can be used for the quantitative determination of HNF in aqueous solutions [253]. The concentration of HNF correlates very well with its optical density at 350 nm within the range 0–8 mg/L with a linear correlation coefficient of 0.9999. This method has the advantages of speed, accuracy, and less expensive equipment, and can be used in the process of synthesis, production, and purification of HNF for quality control and certification.

3.2.5.2 Infrared Absorption Spectra of HNF

The mid-IR spectrum of HNF is shown in Figure 21. Given the structural complexity of solid HNF, the splitting of group vibrational modes was to be expected. The breadth and complexity of the N–H stretching modes results from extensive hydrogen bonding, which causes coupling and Fermi resonances. When solid HNF is squeezed be-

Figure 21: Infrared spectrum of dry, solid hydrazinium nitroformate. (Reproduced from [250]; with permission granted by Dr. Jeroen Louwers, 27 May 2020.)

tween two NaCl plates and heated to the temperature of incipient decomposition, all IR bands were observed to decrease at the same rate. According to the IR spectrum, the only solid product is NH_4NO_3 . There was no evidence for the formation of ammonium nitroformate (ANF) during the rapid thermolysis of HNF.

The best resolution IR spectra of HNF with wave numbers entered at the main peaks were reported by Loebbecke, Schuppler, and Schweikert [254] (Figure 22).

Figure 22: Infrared spectrum of dry, solid hydrazinium nitroformate. (Reproduced and modified from [254].)

The IR spectra of HNF in a KBr matrix pellet have the following absorption bands (with bond assignments and intensities) [255]:

N—H stretch :	3244 cm ⁻¹ (m),
NH ₃ ⁺ deformation :	1615 cm ⁻¹ (w),
NO ₂ asymmetrical stretch :	1512 cm ⁻¹ (s),
NH ₃ ⁺ bend :	1420 cm ⁻¹ (m),
NO ₂ symmetrical stretch :	1271 cm ⁻¹ (s),
NH ₃ ⁺ wagging :	1180 cm ⁻¹ (s),
N—C —N asymmetrical stretch :	1100 cm ⁻¹ (m),
NO ₂ bend :	790 cm ⁻¹ (s),
N—N stretch :	971 cm ⁻¹ (m).

The Dragomir thesis ([256], page 52ff.) contains several IR spectra of the surfaces of burnt and unburnt HNF and a comparison with the spectra obtained by other investigators. A very coarse IR spectrum of HNF was given in Dendage et al. [251], but it is not very useful. The Williams thesis [257] contains an IR spectrum very similar to the one shown in Figure 21.

3.2.5.3 Raman Spectra of HNF

Because HNF rapidly deteriorates under intense white light within the visible range, the Raman spectrum of HNF crystals held in an NMR tube was excited with an IR laser at 1.06 μm (Figure 23).

The band assignments of IR and Raman bands are tabulated in Table 28.

Figure 23: Raman spectrum of dry, solid hydrazinium nitroformate. (Reproduced and modified from [257]; with permission granted by Dr. Graylon K. Williams 22-Mar-2021.)

Table 28: Infrared and Raman band assignments of solid hydrazinium nitroformate.

Infrared	Raman	Assignment

3.2.6 Magnetic Properties of Hydrazinium(1+) Nitroformate

The ¹H NMR spectra (300 MHz, DMSO-d₆ calibrated) of HNF showed a chemical shift of: $\delta = 7.028$ (s, 5H), and the ¹³C NMR spectra (300 MHz, DMSO-d₆) showed a chemical shift of $\delta = 150.759$ (w, 1C) [255]. In ¹H NMR spectra the expected multiplets were not observed because of peak broadening due to intermolecular exchange of hydrogen on nitrogen atoms. The intensity of the ¹³C peak was very weak, though the spectra was recorded for a large number of pulses (2500) with long intervals (1.0 ms). This may be due to the presence of a quaternary carbon atom in the compound.

3.2.7 Thermal Conductivity of Hydrazinium(1+) Nitroformate

The heat capacity, thermal conductivity, and thermal diffusivity of a range of other oxidizers, binders, and rocket propellants was determined and compared with data in the literature [258]. These measurements are difficult because the porosity of

pressed pellets may vary. The thermal diffusivity α of HNF at room temperature is $2.1 \times 10^{-3} \text{ cm}^2/\text{s}$ to $2.2 \times 10^{-3} \text{ cm}^2/\text{s}$ or $1.88 \times 10^{-3} \text{ cm}^2/\text{s}$ at 273 K (0°C). The thermal diffusivity α of HNF can be calculated from the equation

$$\alpha = 1.62 \times 10^{-3} + 1.2 \times 10^{-6} t$$

where α is the thermal diffusivity in cm^2/s and t is the temperature in °C. For comparison, the thermal conductivity λ of HNF measured with the same apparatus at room temperature is $0.686 \times 10^{-3} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ }^\circ\text{C}^{-1}$. The thermal conductivity λ of HNF as a function of temperature can be calculated from the equation

$$\lambda = 2.50 \times 10^{-3} + 6.8 \times 10^{-6} t$$

where λ is the thermal conductivity in $\text{W cm}^{-1} \text{ }^\circ\text{C}^{-1}$ and t is the temperature in °C.

3.2.8 Molecular Structure of Hydrazinium Nitroformate

The molecular structure of HNF, two ions in suspension (not a crystal lattice) is illustrated in Figure 24.

Figure 24: Molecular structure of hydrazinium nitroformate

3.2.8.1 Experimental Study of the Crystal Structure of Hydrazinium Nitroformate

Hydrazinium nitroformate crystallizes in monoclinic crystals that belong into space group $P2_1/n$. The crystal structure of HNF at 113 K (−160 °C) revealed that N_2H_5^+ ions are hydrogen-bonded to neighboring $[\text{C}(\text{NO}_2)_3]^-$ ions [248, 255, 259]. Two crystallographically independent and structurally different formula units are contained in the unit cell. One of the N_2H_5^+ ions is staggered, whereas the other is eclipsed. The $\text{N}-\text{C}-\text{N}$ framework of both $[\text{C}(\text{NO}_2)_3]^-$ ions is planar, but these propeller-shaped ions include dihedral angles between 4 and 74°. The crystal structure parameters are $a = 7.91 \pm 0.02 \text{ \AA}$, $b = 11.77 \pm 0.02 \text{ \AA}$, $c = 13.98 \pm 0.02 \text{ \AA}$, $Z = 8$, $\beta = 104.9^\circ$. The calculated density was 1.93 g/cm^3 . It was concluded that there was extensive hydrogen bonding present within the HNF crystal lattice with 8 units in the unit cell. It was also concluded that the nitroformate anion is non-planar within the HNF crystal and that the precise (crystal) geometry is dependent on the environment. The CN_3 framework of the nitroformate ion may be planar, but the $\text{N}_2\text{C}-\text{NO}$ dihedral angles are between 4 and 74°. This wide

dihedral angle is attributable to the low energy barrier to $-\text{NO}_2$ rotation (typically in the range of 0.3–0.8 kJ/mol). One of the nitro groups is significantly twisted out of the plane of the CN_3 structure. This may allow some degree of freedom of position of the oxygens of the NO_2 group relative to the CN_3 framework, possibly helping to explain the improved stability of the nitroformate structure. The hydrazinium ions present within the cell are hydrogen bonded to neighboring nitroformate ions with two main hydrazinium orientations being suggested. One form has the hydrogen atoms of the N_2H_5^+ ion staggered and the other has the hydrogen atoms of the ion eclipsed.

In addition to XRD, the crystallographic nature and surface chemistry of HNF crystals were examined by SEM, transmission electron microscopy, and X-ray photoelectron spectroscopy (XPS). SEM images showed layered needle-shaped crystals of HNF. The XPS study offered additional information regarding the surface chemistry of HNF and the state of bonding of its C, N, and O atoms. There is evidence of intermolecular hydrogen bonding.

A new (second) HNF modification with a calculated density of 1.938 g/cm^3 was obtained by recrystallizing HNF from ethyl acetate at room temperature [260]. HNF crystallizes in the space group $P2_1/n$ (no. 14) with four formula units per unit cell. The structure reported by Dickens [259] showed two crystallographically independent nitroformate anions with dihedral angles for the nitro groups of 41° , 7° , and 8° for the first anion, and of 74° , 4° , and 5° for the second anion. The two corresponding hydrazinium cations are different and showed staggered as well as eclipsed symmetry of the hydrogen atoms. The newly discovered second modification, however, consists of only one ion pair whereby the nitro groups of the anion have dihedral angles relative to the central C–N3 moiety of 10° , 8° , and 77° , and the hydrogen atoms of the hydrazinium counteranion show a staggered arrangement. The N–N distance in the hydrazinium ion is $1.446(3)\text{ \AA}$, which is in good agreement with the values of the N–N distances of hydrazine cations in the previously described polymorph ($1.44 \pm 0.02\text{ \AA}$ and $1.42 \pm 0.02\text{ \AA}$).

3.2.8.2 Computational Theoretical Studies of the Molecular Structure of Hydrazinium Nitroformate

A variety of computational chemistry methods have been used to predict bond strengths, ion pairing, and dissociation energies of HNF. These methods can also predict reaction paths and eventually ultimate decomposition products.

Discrete Fourier transform methods were used to study the intermolecular interaction of HNF ion pairs [261]. Two fully optimized geometries of HNF ion pairs were examined at the B3LYP/6-31+G** level. The binding energies of ion pairs were corrected for basis set superposition errors and for zero-point energies. The corrected binding energy of the most stable ion pair was predicted to be of the order of -420 kJ/mol . The intermolecular bonds between ion pairs are primarily due to Coulomb interaction but, judged by the electron densities at the bond critical points, covalent interactions also make a remarkable contribution to the bonding. The thermodynamic properties

were calculated based on statistical thermodynamics. The changes of the enthalpy and Gibbs free energy when going from the ions to the most stable ion pair were predicted to be -419.7 and -376.6 kJ/mol at 298 K respectively.

Ammonium nitroformate, ANF, CAS RN [17181-40-7], is an intermediate product of HNF decomposition and may accumulate on the surface of burning HNF pellets. The primary reactions of the thermal decomposition of HNF as well as ANF were investigated theoretically using the G3 multi-level procedure [262]. Calculations were done for the reactions in the gas phase and in the melt and showed that the influence of the melt on the reaction barriers involves the solvation free energies. The most energetically favorable structures of HNF and ANF free molecules in the gas phase are H-bonded complexes. In the melt, the ionic structure is lowest in free energy because of solvation effects. In both the gas phase and the melt, the HNF decomposes preferably to nitroform and free hydrazine. There is no undissociated HNF among the gas-phase decomposition products. Thermolysis of HNF occurs mainly through the intermediacy of nitroform. Contrary to other publications, these computations did not support the suggestion that the *aci*-nitroform is an important intermediate of HNF thermolysis. The primary dissociation reactions of ANF resemble those of HNF. Kiselev and Gritsan is a very good survey article with 77 quite relevant literature references.

Computations of the geometric configuration, weak interaction, and energy characteristics of HNF, ANF, aminotriazolium nitroformate, guanidinium nitroformate (GNF), and aminotetrazolium nitroformate showed that there exist hydrogen bonds in all salts except GNF [263]. The binding energies of the salts were between 390 and 430 kJ/mol and correlated with the densities and thermodynamic stabilities of these compounds, but showed a reverse trend on impact sensitivities. Binding energy calculations indicated that the main interaction between anions and cations is electrostatic interaction. The detonation velocity and specific impulse of five nitroformate salts were predicted to be in the range 8.6–9.1 km/s and 2200–2600 Ns/kg respectively.

3.2.9 Thermodynamic Properties of Hydrazinium Nitroformate

3.2.9.1 Heat Capacity of Hydrazinium Nitroformate

The heat capacity of solid HNF is $0.97 \text{ J g}^{-1} \text{ K}^{-1}$. The heat capacity as a function of temperature in the range 293–383 K (20–110 °C) can be expressed by [258]

$$c_p = 0.198 + 3.41 \times 10^{-4} t$$

where c_p is the heat capacity in $\text{cal g}^{-1} \text{ °C}^{-1}$ and t is the temperature in °C. Heat capacity measurements of HNF pellets by DSC gave the heat capacity curve shown in Figure 25, which can be approximated by a straight line [250]. The specific heat capacity and thermal conductivity were found to have a slight temperature dependence. However, thermal conductivity was found to decrease near the burning surface, owing to cracks during combustion.

Figure 25: Heat capacity of hydrazinium nitroformate. (Reproduced and modified from [250]; with permission granted by Dr. Jeroen Louwers, 27 May 2020.)

3.2.9.2 Heat of Fusion of Hydrazinium Nitroformate

The heat of fusion of HNF at 397 K (124 °C) was estimated to be 29.5 kJ/mol. The entropy of fusion was estimated to be 74.3 J K⁻¹ mol⁻¹ [264].

3.2.9.3 Heat of Sublimation of Hydrazinium Nitroformate

The only reported value for the enthalpy of sublimation of HNF was measured in the temperature interval 307.5–340.8 K (34.4–67.7 °C) and found to be 193.7 kJ/mol (46.3 kcal/mol) [265].

The enthalpy of sublimation may be identical to the enthalpy of dissociation of solid HNF into its gaseous ions, as suggested by the fact that this value is in good agreement with the enthalpy of HNF dissociation ΔH_{diss} (196.19 kJ/mol = 46.89 kcal/mol) calculated from enthalpies of formation of the solid salt (–76.86 kJ/mol = –18.37 kcal/mol from Konkova and Matyushin [266]), gaseous hydrazine (95.19 kJ/mol = 22.75 kcal/mol), and trinitromethane vapor (24.27 kJ/mol = 5.8 kcal/mol). The value for trinitromethane vapor can be taken from Matyushin et al. [267].

The enthalpy of evaporation of liquid HNF (184.9 kJ/mol = 44.2 kcal/mol) can be calculated as the enthalpy of sublimation minus the enthalpy of melting (with an estimated value of 11.3 kJ/mol = 2.7 kcal/mol).

Experimental data of the sublimation temperature, if plotted in the coordinates of log pressure vs reciprocal absolute temperature, yield another value for the enthalpy of dissociation $\Delta H_{\text{diss}} = 155.2$ kJ/mol (37.1 kcal/mol). The sublimation temperature is of-

ten observed on the surface of burning HNF pellets [268]. This value is less than the one calculated. The enthalpy of sublimation of HNF is 156 kJ/mol = 37.4 kcal/mol [269].

3.2.9.4 Heat of Solution of Hydrazinium Nitroformate

The enthalpy of formation of solid salts can be determined more accurately by measuring the heat of solution than the heat of combustion, but only if the enthalpies of formation of the ions forming in aqueous solution are known. This method was used to determine the enthalpies of formation of the potassium, ammonium, hydrazinium, and guanidinium salts of nitroform [266]. The heats of solution of these salts are tabulated in Table 30 along with their enthalpies of formation of the dry salts.

3.2.9.5 Heat of Combustion of Hydrazinium Nitroformate

The heat of combustion of HNF is 5824 kJ/kg = 1392 kcal/kg.

3.2.9.6 Enthalpy of Formation of Hydrazinium Nitroformate

Up until 1998, data reported in the literature for the enthalpy of formation of HNF were quite contradictory. Some of this uncertainty was a fallout of the inaccurate data provided up to that time for nitroform (trinitromethane) [270, 271]. Table 29 gives a summary of values for the enthalpy of formation of HNF obtained from different sources.

The enthalpy of formation of trinitromethyl anion in infinitely diluted aqueous solutions is -24.94 ± 0.79 kJ/mol. It was calculated on the basis of the data obtained for enthalpies of formation and dissolution of the ammonium and hydrazinium salts of nitroform. These data can in turn be used to calculate the enthalpies of formation of the solid salts (Table 30).

Table 29: Enthalpy of formation of hydrazinium nitroformate.

$\text{KC}(\text{NO}_2)_3$	64.10 ± 0.08	-341.18 ± 0.80

Data source: [266]

A renewed determination of the heat of combustion of HNF gave -1031.23 ± 1.13 kJ/mol and the enthalpy of formation of solid HNF derived therefrom is now -76.86 ± 1.13 kJ/mol, which seems to be a reliable value. One of the intermediates in the decomposition of HNF is the ammonium salt of nitroform (ANF). Its enthalpy of formation is -197.90 ± 0.88 kJ/mol [266].

A calculated enthalpy of formation had been reported for a compound that was said to have the formula $[\text{N}_2\text{H}_6][\text{C}(\text{NO}_2)_3]_2$, but it is not known if this salt is stable. Nitroform is a weak acid and may not be able to form doubly ionized hydrazinium(2+) salts.

3.3 Chemical Properties of Hydrazinium Nitroformate

Most organic acids have carboxyl groups. Trinitromethane is a different type of organic acid, without a carboxyl group, but nevertheless an acid because the electron pull of the three nitro groups has weakened the C—H bond. Its hydrazine salt is an oxidizer and is undergoing evaluation as a potential rocket propellant ingredient. It decomposes at its melting point (396 K) and autoignites at 673 K.

Replacing hydrogen in methane or other alkanes with electron-absorbing groups ($-\text{NO}_2$, $-\text{NO}$, $-\text{CN}$) draws electrons away from the remaining C—H bonds and makes them easier to split and more acidic. This progression can be seen when comparing the pK of nitromethane, dinitromethane, and trinitromethane. Among the three, trinitromethane (“nitroform”) is the most acidic and forms salts with a wide range of metals and bases.

3.3.1 Reactions of Hydrazinium Nitroformate

One of the reasons why it was so difficult to find a suitable polymeric binder for HNF-based solid propellants is that HNF readily reacts with isocyanates (hexamethylene isocyanate or *p*-toluene isocyanate) used as curing agents for HTPB. It may also react with residual $>\text{C}=\text{C}<$ double bonds in the skeleton of the binder.

The thermally unstable hydrazinium dinitromethanide was synthesized by denitration of HNF with hydrazine hydrate and fully characterized using IR, Raman, and multi-nuclear (^1H , ^{13}C , ^{15}N) MR spectroscopy, and single crystal XRD as well as thermal, impact, and friction stability measurements [273]. It is not suitable as a propellant ingredient, but may be a contaminant in HNF.

In comparison, other dinitromethanide salts, such as guanidinium, triazolium, and tetrazolium dinitromethanide salts are thermally stable and can be relatively insensitive to impact [274].

3.3.2 Analysis of Hydrazinium Nitroformate

Various analytical methods have been investigated that might be used for HNF quality control during the production process. Acidimetric titration does not give an accurate assay of HNF content. Impurities due to processing liquids, for example, MeOH, dichloroethane, and IPA present in HNF, can easily be detected with NMR or GC-MS.

Impurities that are similar to hydrazine, for example, $\text{N}_2\text{H}_6^{2+}$, or similar to nitroform, for example, dinitromethane, cannot be detected by these techniques.

Other techniques such as high-performance liquid chromatography, FTIR, solid-state NMR, XRD, and capillary electrophoresis are even more limited in their possibilities. A simple technique may be available through UV-visible spectroscopy (see Section 3.3.2.1).

3.3.2.1 Spectrophotometric Analysis of HNF

Hydrazinium nitroformate has two absorption peaks in UV: one around 210 nm and another one at 350 nm (Figure 26). The peak height at 210 nm is roughly the sum of the

Figure 26: Slope of the intensity of hydrazinium nitroformate peaks in ultraviolet. (Reproduced and modified from [210])

hydrazine peak height and nitroform peak height. For three different concentrations of HNF in water, the heights of the 210- and 350-nm peaks may be compared, and when plotting the absorbance versus molarity, the slope of the 210-nm peak height curve is twice the slope of the 350-nm peak height curve (Figure 26). In this way, it may become possible to determine the hydrazine/nitroform ratio in HNF directly, and the measurement is not affected by the presence of other acidic materials as would be the case in acidimetric titrations.

3.3.2.2 Mass-Spectrometric Analysis of HNF

In HNF mass spectra the parent $\text{N}_2\text{H}_5\text{C}(\text{NO}_2)_3$ molecule (mass-to-charge ratio $m/e = 168$) does not appear because of its decomposition prior to vaporization [275]. Fragments were observed in the mass spectrometer at the following m/e values for $\text{NH}_4\text{C}(\text{NO}_2)_3$: 168 (30%); $\text{C}(\text{NO}_2)_3$: 149 (100%); $\text{NH}_4\text{C}(\text{NO}_2)_2$: 122 (18.6%); $\text{HC}(\text{NO}_2)_2$: 105 (16.5%); $\text{NH}_4\text{NO}_3 \cdot \text{H}_2\text{O}$: 97 (9.5%); NH_4NO_3 : 81 (11.4%).

3.3.3 Thermal Stability of Hydrazinium Nitroformate

The thermal stability of HNF is very dependent on the purity of the sample. Excess hydrazine can drastically reduce the stability of HNF.

The decomposition of HNF leads to nitrogen, carbon dioxide, water and oxygen.

HNF is thus an oxidizer because it has extra oxygen beyond that which is required to burn all hydrogen and carbon in the molecule. The decomposition reaction is exothermic, such that HNF solutions could be used as monopropellants if sufficient oxidizer could be dissolved in water.

One of the earliest publications on the thermal decomposition of HNF is the Koroban paper [275]. They studied HNF decomposition under isothermal conditions within the temperature interval from 333 to 373 K (70–100 °C), i.e., below the melting point ($E_a = 169.6 \text{ kJ/mol}$ or 40.5 kcal/mol and $A = 10^{17.6} \text{ s}^{-1}$ for the initial decomposition; $E_a = 144.8 \text{ kJ/mol}$ or 34.6 kcal/mol , $A = 10^{16.1} \text{ s}^{-1}$ for autocatalysis during the end). The activation energy for the overall thermal decomposition of HNF was estimated to be 180 kJ/mol (43 kcal/mol). The reaction products consisted of N_2 , N_2O , CO_2 , and H_2O , and the decomposition is accelerated by autocatalysis. A mechanism was proposed that involved two parallel processes: **(1)** cleavage of $\text{C}(\text{NO}_2)_3^-$ to $[\text{C}(\text{NO}_2)_2]^-$ and NO_2 , followed by reaction of N_2H_5^+ with the two products, and **(2)** interaction of HNF with N_2H_4 . The enthalpy of dissociation of HNF to N_2H_4 and $\text{CH}(\text{NO}_2)_3$ was 171 kJ/mol (41 kcal/mol), very similar to the activation energy for the decomposition.

A study of HNF decomposition under non-isothermal, “combustion-like” conditions in the range from 403 to 673 K (130–400 °C) gave an activation energy of $E_a = 104.6 \text{ kJ/mol} = 25 \text{ kcal/mol}$ and a frequency factor of $A = 10^{11.03} \text{ s}^{-1}$ [276].

In TGA, the first-stage decomposition (temperature range: 378–415 K [105–142 °C]) showed 72.5% weight loss, whereas in the second stage of decomposition (temperature range: 415–483 K [142–210 °C]) the weight loss was 24.5%. FTIR analysis of the off-gassing during thermal decomposition indicated the formation of some cyanamide-like species.

Hydrazinium nitroformate decomposition was examined between 403 and 673 K (130 and 400 °C) by T-jump/FTIR spectroscopy, which included melt/foam decomposition and self-ignition regimes [257]. Reaction regimes included evaporation, conversion to $\text{NH}_4\text{C}(\text{NO}_2)_3$ and progressive decomposition to CO_2 , CO, N_2O , NO, and H_2O . Induction-time decomposition kinetics gave an activation energy of $E_a = 104.6 \text{ kJ/mol}$ (25 kcal/mol) and a natural logarithm of the frequency factor of $\ln(B, \text{s}^{-1}) = 25.3$ of the melt/foam layer. These values agreed reasonably well with previously reported temperature-profile data. HNF samples on a platinum ribbon were heated rapidly (600 °C/s) to a pre-selected temperature (413–673 K = 140–400 °C) and flash-pyrolyzed and the evolution of gaseous decomposition products was measured by shining an IR beam through the cloud of products and recording the absorption with an FTIR instrument. The composition of products changes quickly with time and pre-set target temperature and allows some conclusions about the decomposition mechanism and intermediate products of combustion. Because the platinum ribbon voltage fluctuates while an endo- or exotherm is in progress, the onset temperature of an endo-/exotherm can be measured, but the quantity of heat released is more difficult to estimate (this is not DSC because the sample holder is wide open). No flame is created in this experiment because it is the objective to study the decomposition at the preset target temperature of the heating filament. Free trinitromethane and hydrazine vapors were identified in the vapor space above decomposing HNF. No $\text{NH}_3(\text{G})$ was detected.

Samples of ANF were subjected to the same conditions to see if they could survive (they did not). In a separate TGA experiment, ANF decomposed in a two-step process, where the first step at 385 K (112 °C) corresponded to the decomposition/sublimation of ANF and the second (centered at 443 K = 170 °C) corresponded to the decomposition of NH_4NO_3 .

Several analysis methods were applied to the study of HNF thermal decomposition at 313–353 K (40–80 °C) [277]. These methods included TGA combined with mass spectrometry (TGA-MS), headspace GC-MS, NMR, FTIR, and DSC. Samples were kept under isothermal conditions and the evolution of decomposition products was followed as a function of time.

The decomposition of solid crystalline HNF was investigated by heating small samples (0.5 g) of the material in closed septum-sealed glass vials (10 cm³ capacity) at temperatures between 60 and 80 °C [278]. Gases evolved from the decomposition were captured and analyzed by headspace GC-MS over a range of ageing times at each temperature. Condensed-phase residues were investigated by FTIR spectroscopy and by NMR spectroscopy. Under all conditions, the major gas detected was nitrous oxide

(N₂O). Only in the latter stages of ageing at the higher temperatures could other gases, notably nitrogen and carbon dioxide, be observed. ¹H and ¹⁴N NMR analysis indicated that the hydrazinium ion is lost very rapidly from the HNF at the higher temperatures and that ANF is the principal initial solid product. The formation of ANF was also supported by the observed changes in the 1400- to 1500-cm⁻¹ region of the FTIR spectrum of HNF during ageing. On the basis of these results, an overall decomposition reaction of HNF has been proposed as follows:

See also [279].

Differential scanning calorimetry in open Al crucibles and TGA/DTA of two HNF samples (different grades and batch numbers) showed the onset of melting at 404 K (131 °C) and the onset of exotherm and decomposition at 407–408 K (134–135 °C). The mass loss at the end of complete decomposition was 97.4 to 98.3% [207, 245].

A thermoanalytical study of HNF to determine the exotherm(s) of HNF decomposition and the time-resolved detection of thermal decomposition products by IR spectroscopy evolved gas analysis (IR-EGA) revealed the formation of a product with an IR spectrum not much different than the spectrum of HNF [254]. This product was identified as ANF, because the characteristic IR functionality of ammonium ion NH₄⁺ was found as a sharp peak centered at 3237 cm⁻¹. The presence of ANF has also been confirmed by the disappearance of N–N stretch absorption around 950 cm⁻¹ of the hydrazinium group, thus explaining its transformation to an ammonium. Besides ANF, small amounts of CO₂ and N₂O as well as ammonia and nitroform have been detected as decomposition products of HNF. At temperatures above 493 K (220 °C), only CO₂ and N₂O and some traces of water were detected as the final IR-active decomposition products. The absence of NO₂ formation during the entire decomposition process should be noted and this contradicts observations by others. The absence of NO₂ could be explained by its instant reaction with HNF:

Based on TGA measurements, the decomposition of HNF at high heating rates is a two-step process (Figure 27). This figure shows the mass loss and the rate of mass loss at a heating rate of 10 K/min.

The effect of different heating rates on the onset of exotherm and the shape of the thermograms of HNF decomposition in a DSC is shown in Figure 28. The onset of exotherm was 391 K (118 °C) at 0.5 K/min., 395 K (122 °C) at 1 K/min., and 398 K (125 °C) at 2 K/min.

The thermal stability of HNF was measured by DSC with a heating rate of 5 °C/min in closed vessels that could withstand a pressure of about 80 bars [280, 281]. Two grades of HNF were tested: an S and an E type, referring to their production techniques (solvent/non-solvent and evaporative crystallization respectively). By applying different heating rates, an analysis of the decomposition kinetics could be performed to give

Figure 27: Thermogravimetric analysis of hydrazinium nitroformate decomposition; mass loss (solid line) and mass loss rate (dashed line). (Reproduced and modified from [254].)

Figure 28: Effect of different heating rates on the onset of exotherm and shape of the differential scanning calorimetry thermogram of hydrazinium nitroformate decomposition. (Reproduced and modified from [254].)

additional information on the activation energy of the decomposition process and the predicted shelf-life of the material, when it is stored at above normal temperatures. The DSC showed that immediately after an endothermic effect, a strong exothermic effect occurs, starting at 398.5–399.2 K (125.4–126.1 °C). It was concluded that there is

a single reaction occurring for this decomposition process. The averaged kinetic parameters for the process are:

$$E_a = 226.2 \frac{\text{kJ}}{\text{mol}} \quad A = 5.44 \times 10^{27} \text{ s}^{-1} \quad n = 1$$

In addition to DSC and DTA/TGA, samples of HNF were analyzed in a microcalorimeter for signs of premature decomposition [282].

Hydrazinium nitroformate has a much higher heat of explosion than AP, 5579 J/g compared with 1972 J/g for AP. All advantages together could allow us to make HNF-based propellants with better performance than AP-based propellants. However, a disadvantage is the poor thermal stability of HNF, which is much worse than that of AP. Therefore, an extensive investigation was performed on the thermochemical stability of HNF. Three sample lots of HNF of different purity were investigated at Fraunhofer Institute of Chemical Technology (ICT), and its thermal stability was determined by five methods [283, 284]: **(1)** autoignition temperature with 0.2 g at 5 °C/min heating rate of the Wood's metal bath, **(2)** vacuum stability test, **(3)** mass loss as function of time and temperature, **(4)** heat generation rate as function of time and temperature, and **(5)** adiabatic self-heating rate. All curves from both methods indicated self-accelerating behavior described with autocatalytic reaction kinetic models. The Arrhenius parameters were determined for one production lot from mass loss data and for two other lots from heat generation data. The activation energies for the intrinsic decomposition reaction were 166, 139, and 132 kJ/mol and for the autocatalytic reaction they were 159, 128, and 117 kJ/mol. The frequency factor was $A = 10^{13} \text{ s}^{-1}$. There was a significant difference between the three lots investigated. These data can be used for calculating the lifetime at different storage temperatures.

The thermal decomposition of HNF was analyzed using TGA, TGA-FTIR, DTA, and DSC [285]. The purity of the synthesized HNF was determined by high-performance liquid chromatography, and the synthesis product was further characterized by elemental analysis, UV, IR, ^1H NMR, ^{13}C NMR, and electron impact mass spectroscopy. DTA, TGA, and DSC results indicated a two-stage decomposition of HNF. The DSC thermogram (Figure 29) exhibited two exotherms with a maximum temperature of decomposition (T_{max}) at 409 and 411 K (136 and 138 °C) respectively. Decomposition temperatures of these exotherms were in close agreement with the data reported earlier by Schöyer et al. [247].

The energy of activation for the first and second exotherms for both stages of decomposition obtained from the data generated at different heating rates was 150 kJ/mol, with pre-exponential factors of 1.3×10^{19} and 1.5×10^{19} respectively. This activation energy was close to that reported by Williams and Brill [276]. In TGA the first-stage decomposition (temperature range: 378–415 K [105–142 °C]) showed a weight loss of 72.5%, whereas in the second stage of decomposition (temperature range: 415–483 K = 142–210 °C) the weight loss was 24.5%.

Figure 29: Thermogram of thermal decomposition of hydrazinium nitroformate. (Reprinted and modified from [251] with permission from © 2003 Taylor Francis Ltd., <http://www.tandfonline.com>)

Results of earlier decomposition studies using T-jump/FTIR by Williams and Brill [276] for the fast decomposition of HNF in the range 123–260 °C with identification of the intermediate products agreed with later results by Schöyer et al. [210] for H_2O , CO , NO , and N_2O , and the absence of NO_2 ; but whereas Williams and Brill also detected ANF aerosol, $\text{HC}(\text{NO}_2)_3$, and N_2H_4 , these were not observed by Dendage et al. [251] during the TG-MS measurements at 393 K = 120 °C. On the other hand, Williams and Brill did not report the presence of NH_3 , OH , N_2 , HCHO , O_2 , and CO_2 . In fact, Williams and Brill stated that CO_2 was only detected above 533 K = 260 °C. The differences may be due to different experimental conditions (393 K = 120 °C isothermal vs 396–533 K = 123–260 °C ramp-up, different heating rates, and different analysis techniques), but it may also be that the improvements in the purity of HNF itself affected the products of decomposition. The most likely first step in the decomposition mechanism of HNF is a proton transfer, after which N_2H_4 and HONO are released.

Samples of HNF (~0.5 g) were sealed in air in glass vials and maintained at the appropriate ageing temperature of 333, 343, and 353 K (60, 70, and 80 °C) [286]. After set periods of time the individual vials were removed from ageing and cooled in a refrigerator until completion of the rest of the samples. Analysis of all the vials from a given temperature trial was carried out at the same time after ageing of the whole series was completed. Analysis of the decomposition gases was performed by headspace GC-MS. As is seen from the GC-MS data, nitrous oxide is the main decomposition gaseous product (Figure 30). However, at that time the identity of possible carbon-containing product(s) from HNF decomposition was still unresolved.

Figure 30: Product gases from hydrazinium nitroformate aged at 343 K (70 °C). (Reprinted and modified from [286], with permission from Dr. Alessandro Ciucci 19 July 2020.)

Single and double (asymmetrical) methyl substitution on hydrazine, using MMH or UDMH instead of hydrazine or hydrazine hydrate for neutralization of trinitromethane, yields the MMH and UDMH salts of trinitromethane, abbreviated as monomethyl hydrazinium nitroformate MMHNF and dimethyl hydrazinium nitroformate (DMHNF), analogs to HNF that are thermally more stable and less impact sensitive than HNF [287]. The new compounds were characterized by elemental analysis, IR, NMR, TGA, and DTA, and their theoretical performance as explosives was calculated. The properties of the three salts are compared in Table 31. The activation

Table 31: Properties of hydrazinium nitroformate (HNF) and its methyl-substituted derivatives.

Properties	HNF	MMHNF	DMHNF
Melting point °C	120–122	128–130	137–140
Activation energy of decomposition (kJ/mol)			
First step	223	245	265
Second step	110	134	149
Impact sensitivity (50%, height, cm)	20	30	35

For comparison:

MMHNF = monomethyl hydrazinium nitroformate, DMHNF = dimethyl hydrazinium nitroformate

Data source: [287]

energies of thermal decomposition increase with increasing methyl substitution, indicating that the methyl-substituted compounds are thermally more stable than HNF.

A study of the degradation of crystalline HNF and HNF/polyNiMMO propellants showed that the contribution of gas/solid autocatalysis in the degradation of the crystalline phase was very low [288]. GC-MS analysis results suggested that the presence (and eventual release) of a solvent impurity, isopropyl alcohol, is a significant contributor to the eventual autocatalytic breakdown of the crystal matrix. It appeared that a significantly different reaction scheme dominates the events at 353 K (80 °C) compared with either 333 or 313 K (60 or 40 °C). Hydrazine scavengers would be expected to improve the thermal stability of HNF.

Three sample lots of HNF provided by Aerospace Propulsion Products BV, The Netherlands, were investigated at ICT in Germany [289]. The thermal stability was determined by autoignition temperature with 0.2-g samples at 5°/min heating rate in a Wood's metal bath, vacuum stability test (VST), heat generation rate as a function of time and temperature, mass loss as a function of time and temperature, and adiabatic self-heating rate. Two lots were characterized by heat generation rate and by mass loss at 333, 338, 343, and 348 K (60, 65, 70, and 75 °C). Samples from another lot were extensively used for mass loss determinations in the temperature range from 323 to 353 K (50 to 80 °C). All samples showed high heat generation rates and self-accelerating autocatalytic decomposition behavior. There was a substantial lot-to-lot variation. The Arrhenius parameters were determined from mass loss data and from heat generation data.

Rate constants of the dominant HNF combustion reaction in the pressure range of 0.04–1 MPa were obtained from the Zeldovich expression, taking the surface temperature as the ANF dissociation temperature [249]. The average specific heat was taken as 1.67 kJ kg⁻¹ K⁻¹ (0.4 cal g⁻¹ °C⁻¹), the thermal diffusivity of the condensed phase as 1.35 × 10⁻⁷ m² s⁻¹, the density of the sample as 1.74 g/cm³, and the heat of melting as 11.3 kJ/mol (2.7 kcal/mol). As illustrated in Figure 31, the results derived from this combustion model for the temperature range 550–675 K,

$$k = 10^{14.43} \cdot \exp(-18400/T), \text{ s}^{-1},$$

marked by gray dot symbols, are in satisfactory agreement with the rate constants of HNF decomposition reported by others.

Data points (solid black dots) obtained from the Sinditskii combustion model fall on the dashed line drawn through data extrapolated to the high-temperature area. Decomposition data obtained by Williams and Brill [276] and de Klerk, van der Heijden, and Veltmans [280] differ considerably from data of other investigators (Wingborg and van Zelst [207], Bohn 2005 [283, 284] and Sinditskii et al. [268] and [269]). This may be due to some methodical mistakes of measurement of the decomposition rate or different quality of the chemicals used.

Figure 31: Comparison of rate constants of the leading reaction of hydrazinium nitroformate combustion and rate constants of hydrazinium nitroformate decomposition reported by several authors. Source identification: (1) black dots and dashed line Sinditskii et al. [249], (2) = Koroban et al. [275], (3) = Bohn 2005 [283], (4) = Wingborg and van Zelst [207], (5) = Williams 1995 [276], and (6) = de Klerk, van der Heijden, and Veltmans [280].

The thermal decomposition of HNF was studied by DSC, TGA, and a VST [290]. Based on the peak temperatures of DSC curves and conversion degrees (α) of TGA curves at 5, 10, 15, and 20 °C/min, the apparent activation energy (E_k and E_a) and pre-exponential factor (A_k) for the thermal decomposition reaction of HNF were calculated by two different methods, the Kissinger method and the Ozawa method. Thermodynamic parameters (free energy of activation ΔG , enthalpy of activation ΔH , and entropy of activation ΔS) for thermal decomposition reaction of HNF and thermal safety parameters (critical temperature of runaway thermal explosion T_{bpo} and self-accelerating decomposition temperature T_{SADT} for HNF) were calculated. The volume of gas evolved from HNF decomposition in the VST was 0.41 mL/g, which does not exceed the standard of 2 mL/g, indicating that HNF has good thermal stability. The exothermic decomposition process of HNF after melting can be divided into two stages: $E_k = 257.10$ kJ/mol, $A_k = 1.74 \times 10^{33}$ s⁻¹, $\Delta G = 103.37$ kJ/mol, $\Delta H = 253.82$ kJ/mol, $\Delta S = 380.78$ J · K⁻¹ · mol⁻¹, $T_{bpo} = 400$ K, and $T_{SADT} = 395$ K. The kinetic equation of

exothermic decomposition reaction may be described as follows: for the first stage in the α range of 0.20~0.65:

$$\frac{d\alpha}{dt} = kf(\alpha) = A \exp\left(\frac{E}{RT}\right) f(\alpha) = 5.14 \times 10^{21} \times (1 - \alpha) [-\ln(1 - \alpha)]^{\frac{1}{2}} \exp(-1.81 \times 10^4/T),$$

and for the second stage in the α range of 0.65~0.80:

$$\frac{d\alpha}{dt} = Kf(\alpha) = A \exp\left(\frac{E}{RT}\right) f(\alpha) = 3.30 \times 10^{14} \times (1 - \alpha) [-\ln(1 - \alpha)]^{-1} \exp(-1.33 \times 10^4/T).$$

3.3.3.1 Vacuum Stability of Hydrazinium Nitroformate

For the vacuum stability test, a sealed and evacuated tube containing the sample and connected to a mercury manometer was immersed in a thermostatted bath at 343 K (70 °C) for 48 h [245]. The gas evolution from two different samples differed by more than a factor of 1.6, indicating potential contamination of one of the samples. The more stable sample developed 0.58 mL of gas, whereas the impure sample evolved 0.93 mL of gas. These data indicate that HNF is much less stable than other oxidizers (AP or RDX). Similar vacuum stability tests were also performed on HNF in combination with various solid propellant binders.

3.3.3.2 Kinetics of Hydrazinium Nitroformate Decomposition

Various kinetic paths for the decomposition of HNF have been proposed, based on analysis of intermediate and ultimate products.

Quantum chemical calculations confirmed that the proton transfer has the lowest energy barrier (activation energy 84 kJ/mol) [250]. According to these calculations, this is followed by a reaction between the *aci* nitroform and N_2H_4 .

Koroban et al. [275] and Williams and Brill [276] discovered ANF as a product of HNF decomposition. The enthalpy of ANF dissociation, 164.77 kJ/mol (39.38 kcal/mol), is less than that of HNF and agrees closely with the experimental value. Based on this fact, the surface temperature of burning HNF was proposed to be determined by dissociation of ANF as a product of the condensed-phase reaction [291].

For the mechanism of HNF transformation in the condensed phase it has been suggested that the HNF decomposition process might comprise the nitroform decomposition reaction with high activation energy and concurrent reactions of lower activation energy between radicals formed in nitroform destruction and hydrazine moieties of neighboring HNF molecules. The heat produced by the total reaction was estimated as $Q = 1674$ kJ/kg (400 cal/g). The result of a considerable amount of heat generated in the HNF condensed phase is also attested by the ability of HNF to sustain burning at low pressures in the absence of the gas flame [268, 269].

Reacting species including N_2H_4 , NH_3 , and N_2O were known to be present near the surface of burning HNF since the early investigation of HNF combustion. In addition, planar laser-induced fluorescence from the near surface region of burning HNF pellets

indicated the presence of NO_2 as a reaction intermediate [292]. These four species are formed in the upper (foamy) layer of the solid phase.

3.3.3.3 Thermal Stability of Hydrazinium Nitroformate Mixtures with Other Energetic Materials

In an effort to improve the thermal stability of HNF, it was mixed in a 1:1 mass ratio with HMX, hexanitrohexaazaisowurtzitane (HNIW), triaminotrinitrobenzene (TATB), and tetranitrodibenzo tetraazapentalene (TACOT), all thermally stable high-energy explosives, and the thermal stability of the mixtures was measured by DSC [251]. HNIW and HMX decomposing in the temperature range 523–553 K (250–280 °C) did not influence the decomposition of HNF and *vice versa*. The more stable TATB and TACOT decomposing at 633–683 K (360–410 °C) also did not show any interaction with HNF. The DSC thermograms at 10 °C under GN_2 showed three nicely resolved exotherms, two for HNF in the range 403–423 K (130–150 °C) and one for the other compound well above 523 K (250 °C).

3.3.4 Storage Stability of Hydrazinium Nitroformate

Storage stability of HNF depends, among other factors, on purity and/or contamination. Several analytical methods were used to determine the hydrazine and nitroform content of HNF. Because it was demonstrated that excess hydrazine in HNF strongly affects HNF stability, such analytical methods are important for quality control.

A sample of HNF prepared by Rocketdyne and stored at AFRL at Edwards AFB for more than 20 years under CCl_4 had a melting point of 390–391 K (117–118 °C), close to that of the original material.

Examination of HNF in sealed and unsealed environments indicated that samples in sealed containers degraded at a higher rate than those in open containers. This suggests some degree of autocatalysis in the degradation of the HNF molecule where preliminary degradation species re-attack other HNF molecules within the bulk material. Vacuum thermal stability testing of HNF confirmed this acceleration of degradation rate during storage with the total gas volume measured showing exponential growth during storage. VTS data for HNF gas evolution during ageing generally show an initial rapid evolution of gaseous products followed by a near plateau region. Following this plateau, autocatalysis eventually starts to occur. This profile is more accelerated at increased storage temperature. The first rapid increase is often attributed to solvent or impurity loss. The slow natural decomposition of HNF during storage was demonstrated to be a first-order reaction. The storage stability is measured by VTS tests at 333 K (60 °C) [210]. In most of the VTS tests it was observed that the major gas evolution took place during the first 1.5 h (or less); usually the amount of gas increased by not more than twice the initial gas evolution during the remainder of the 48 h. This is an indication that much of the gas evolution is due to the evaporation of processing and washing liquids that adhere to the surface of the HNF crystals or to adhering free

hydrazine. By the introduction of more washing and drying cycles, the VTS gas evolution decreased dramatically. For example, one wash/drying cycle led to an initial VTS (333 K = 60 °C, 1.5 h) of 0.54 mL/g, which, after 48 h, had increased to 0.94 mL/g; three washing and drying steps improved these values to ~0.18 and 0.36 mL/g respectively.

The time to produce 3 mL of gas per gram of HNF was measured at 333, 353, and 363 K (60, 80, and 90 °C), as well as the point where the reaction started to run away. Two different types of HNF gave the same activation energy (slow decomposition 157 kJ/mol, run-away 147 kJ/mol), confirming that the slow (low-temperature) decomposition of HNF is essentially a first-order reaction. One may use these data to estimate the time to generate 3 mL/g gas during normal storage conditions at room temperature, that is, at 293 K (20 °C). The predicted storage life was 712 to 610 years respectively, for two samples of different pedigree.

3.3.5 Stabilizing Additives for Hydrazinium Nitroformate

Already soon after the discovery of HNF as a propellant ingredient the lack of thermal stability was recognized as a potential problem. It also became apparent that the instability was caused by excess hydrazine. From the large number of publications about possibly suitable stabilizers for HNF, it appears that finding a stabilizer that really works and outlives the patent claims would be a worthwhile effort, but it has been an elusive target for a long time. A drawback of the use of stabilizers in a rocket propellant is that they add inert mass to the fuel and decrease the performance because they do not contribute to the supply of energy.

Numerous publications from the 1960s and 1970s indicate that HNF produced in this way did not exhibit the desired stability. As described in US Pat. No. 3418183 [293], the hydrazine nitroform tends to form bubbles, or, as it is called, the hydrazine nitroform “gasses” during storage. This tendency to “gas” is attributed to the impurities of the hydrazine nitroform produced. As the years progressed, numerous patents followed that suggested various stabilizers. Besides US Pat. 3418183, where anhydrides of dicarboxylic acids (preferably a dodecenyl succinic acid anhydride) were proposed, the proposed stabilizing additives included nitroguanidine [294]. Another patent disclosed the addition of non-volatile aldehyde compounds such as benzaldehyde as hydrazine getters for increasing the stability of hydrazine nitroform [295]. Non-volatile aldehydes would form azines that bind the hydrazine liberated by HNF decomposition in a harmless form. Other patents disclose the stabilization of HNF with oxalates [296], salts of oxalic, phosphoric, or phosphorous acid, or an excess of nitroform [297].

3.3.6 Thermal Decomposition of Hydrazinium Nitroformate Solutions

Solubility of HNF in water is only 50 mass-%. It is unlikely that the catalytic decomposition of HNF solutions by themselves in the absence of fuels will ever find rocket propulsion applications, but it is a very important initial step in the application of HNF-based monopropellants in catalytic reactors, regardless of the type of fuel

present. In addition, the thermal stability of HNF solutions has to be known because concentrated HNF solutions are heated during recrystallization and purification of the material.

The thermal stability of 65/35 HNF/H₂O solutions was investigated and tests showed that boiling started at 373 K (100 °C). At 383 K (110 °C), a pH indicator paper strip turned red, indicating evolution of acidic vapors with a pH around 1–2 owing to decomposition of HNF in hot water [210]. Recrystallization of HNF from water must be done at low temperatures.

Aqueous solutions of 40% HNF were thermally and catalytically decomposed on Pt/SiO₂ catalysts and the results were compared with similar tests performed with 40 and 79 mass-% HAN solutions [298]. The reactions were tracked by TGA and DTA and the reaction products withdrawn from a batch reactor were analyzed by mass spectrometry. In the presence of a catalyst, HAN displayed a single exothermic peak whereas HNF showed two separate exotherms. Figure 32 shows the thermogram of decomposing 40% HNF solutions. The main exotherm starts at about 393 K (120 °C).

Figure 32: Thermal decomposition of 40 mass-% hydrazinium nitroformate solution. (Reprinted and modified from [298], with permission from Dr. Charles Kappenstein.)

3.3.7 Catalytic Decomposition of Hydrazinium Nitroformate Solutions

The catalytic decomposition of HAN (20, 40, 79 mass-%) and HNF (about 40 mass-%) solutions was compared in a constant volume reactor with differential thermal monitoring [299]. Comparing the reactivity of the two oxidizers with the same catalyst, HNF

solutions gave lower performances than HAN solutions, suggesting that other catalysts need to be invented for this oxidizer.

3.4 Strand Burning of Hydrazinium Nitroformate

The surface temperature of burning HNF is strongly dependent on the pressure at which the combustion takes place. HNF can burn as a compressed pellet or as a melt in a quartz tube at atmospheric pressure. The combustion of HNF is different from the very slow natural decomposition that is a first-order reaction, whereas the combustion reaction is roughly between one and one-half and second order. The strand burning is sometimes called “deflagration.” Neat HNF shows self-sustained combustion at pressures above 0.025 MPa.

The dependence of the burning rate as a function of pressure and temperature is a valuable design parameter, either using HNF by itself or using HNF with a binder. The burning rates of solid propellants formulated with HNF and a binder will be discussed in future volumes.

The combustion products of HNF have a low molecular weight and a high flame temperature because of the low C:H ratio and high enthalpy of formation. HNF has 13% excess oxygen and its combinations with binders as fuels have even higher flame temperatures and better performance as a rocket propellant. It has the advantage over other solid propellant oxidizers that it does not create hydrogen chloride in the exhaust gases, making it environmentally more friendly.

3.4.1 Experimental Determination of Strand Burning Rates of Hydrazinium Nitroformate

One of the first burning rate measurements with pressed pellets of HNF was reported in 1964 [300]. Granular HNF was tamped into glass tubes and the deflagration rates were measured at pressures of 0.02 to 6.88 MPa (3 to 1000 psia). Rates were independent of tube diameter, increased linearly with pressures 138 kPa (20 psia), and were independent of pressure at low pressures. Quenching occurred below critical tube diameters ranging from 0.3 cm at 13.8 kPa (2 psia) to 0.01 cm at 6.88 MPa (1000 psia).

The deflagration of solid HNF has been studied at pressures of 21–6900 kPa (3–1000 psia) and compared with that of AP and HAP [246]. HNF sustains deflagration in a tube down to a pressure of at least 25.2 kPa (0.25 atm) and also exhibits an upper pressure limit at 7.07 MPa (70 atm). No burning rate dependence on tube size was observed as long as the diameter was above the quenching diameter by a factor of at least 1.5. Material compacted to 1.1–1.5 g/cm³ (considerably below crystal density of 1.87 g/cm³) burned at 0.1 cm/s at atmospheric pressure. The pressure exponent is $n = 1.0$ above 202 kPa and less than 1 below 101 kPa.

In a later investigation, the density of pressed HNF pellets used for burning rate studies was 1.740 g/cm^3 . Experimental observation showed that the burning surface temperature was $T_s = 523 \text{ K}$ and the linear burning rate was $r_b = 0.77 \text{ mm/s}$ at 0.1 MPa [301].

There are many experimental methods for studying the burning rate of energetic materials and their response to chamber pressure oscillations. One method uses ultrasound to sense the location of the regressing solid surface [302]. This is similar to an echo sounding for the bottom of the ocean. Another method is to illuminate the burning surface with a laser, steady-state or modulated to see how the burning material responds to the additional non-chemical energy input.

As part of the study of the transient combustion of HNF, laser-assisted regression rates of HNF were determined for a narrow range of chamber pressures from 1 to 6 atm [303]. HNF crystals were pressed into pellets with densities of 1.774 g/cm^3 , which is 94.9% of the theoretical maximum density of 1.87 g/cm^3 . The pellets were burned by themselves (no fuel added) in an IR $10.6\text{-}\mu\text{m}$ CO_2 laser recoil device at pressures from 101 to 606 kPa (1 to 6 atm) and the recoil force was measured with a sensitive load cell. During combustion the laser energy is absorbed in the condensed phase near the burning surface and locally increases the regression rate. The laser-assisted regression rate data allowed further validation of combustion models, in particular, those attempting to explain combustion instabilities. The laser flux was set at two different mean power levels with sinusoidal oscillations of $21 \pm 11.5 \text{ W/cm}^2$ or $52 \pm 5.9 \text{ W/cm}^2$. Oscillations were logarithmically swept over the range from 4 to 80 Hz. Burn rate vs laser flux was measured up to 60 W/cm^2 at 101 to 606 kPa (1 to 6 atm) pressure. The slope of the burn rate vs laser flux was nearly the same at each pressure. Ignition delay times decreased from 760 to 78 ms as the laser flux increased from 21 to 67 W/cm^2 . Ignition times also decreased with increasing pressure. HNF burned nicely with a steep burn rate slope of 0.892 down to 34 kPa (5 psia). The burn rate data fit the equation $r = B \cdot P^n$, where r is the burning rate in cm/s, $B = 0.00666$, n is the pressure exponent = 0.892, and P is the pressure in psia.

Louwers and others have also done steady and transient combustion modeling for HNF burning [304–306]. HNF burned with a high regression rate (40 mm/s at 10 MPa) and a high burn rate exponent. A slope break was observed around 2 MPa . (From $n = 0.95$ to $n = 0.85$). The surface temperature T_s increased with increasing pressure: at 0.1 MPa $T_s = 530 \text{ K}$, and at 1 MPa $T_s = 680 \text{ K}$. Thermocouple measurements showed a bend in the condensed phase temperature profile. This bend was attributed to cracks that form during combustion. At low pressures, a small amount of residue was found after combustion of these samples. However, at 2 MPa the pellets combusted without residue. Samples containing 5% graphite had a constant pressure exponent of $n = 0.81$. At around 10 MPa , the burn rate became equal to that of neat HNF. Also, paraffin-based combinations burned with a low pressure exponent $n = 0.81$ at low pressure. Samples containing 20% aluminum powder had a burn rate at 1 MPa that was about 30% higher than that of neat HNF.

The strand burning rates of HNF were compared with those of ADN, RDX, HMX, CL20, and AP [307]. Cylindrical pellets (6.6 mm in diameter) of HNF were pressed under dry air conditions at 6.21 MPa for 5 min. The density of the resulting pellets was 93–95% of theoretical maximum density. Like ADN, HNF has a low melting point (398 K), restricting the evaluation of burning rate temperature sensitivity over a wider range of temperatures. The ambient temperature burning rates obtained at the Naval Air Warfare Center Weapons Division (NAWCWD) are compared with data from the Atlantic Research Corporation (ARC) in Figure 33.

Figure 33: Strand burning rates of hydrazinium nitroformate at room temperature; Comparison of Naval Air Warfare Center Weapons Division and Atlantic Research Corporation data. (Republished and modified from [307] with permission of American Institute of Aeronautics Astronautics; permission conveyed through Copyright Clearance Center, Inc.)

The ARC burning rate data were generated using straws filled with HNF powder instead of pressed pellets; thus, the combustion at pressures of 2 MPa and higher may be more representative of convective burning rather than a laminar burn. Elsewhere, the burning rates are comparable. The HNF burning rate data at three initial temperatures (223, 298, and 348 K) are presented in Figure 34 for pressures from 0.69 to 10.3 MPa. The three curves are very close to each other.

Figure 34: Strand-burning rates of hydrazinium nitroformate at three different temperatures. (Republished and modified from [307] with permission of American Institute of Aeronautics Astronautics; permission conveyed through Copyright Clearance Center, Inc.)

In extending these burning rate and pressure exponent measurements, additional data were used to determine the temperature sensitivity coefficient σ_p of the burning rate of HNF and four other oxidizers [308].

The simplest means of determining a value of σ_p is to measure the burning rate of a particular material as a function of initial temperature, take the natural logarithm of the burning rate values, and determine the burning rate temperature sensitivity as the slope of the line through a plot of the natural logarithm of the burning rate vs the initial temperature. The main requirement is to obtain a consistent and reliable set of burning rate data at various initial temperatures and pressures. In the case of HNF, the temperature sensitivity remains essentially flat over a wide pressure range (Figure 35).

The burning rate of HNF pellets measuring 6 and 9 mm in diameter was determined in two different strand burner bombs and the data were plotted together on the same graph (Figure 36) and compared with literature data from the Naval Air Warfare Center [250]. This is part of a PhD thesis that contains a very thorough investigation of many aspects of HNF decomposition and combustion.

The burn rate curve shows a slight slope break around 2 MPa from $n = 0.95$ going to $n = 0.85$ at higher pressures. Below 2 MPa, no inhibitor was used on the outside of

Figure 35: Temperature sensitivity coefficient of strand-burning rate of hydrazinium nitroformate. (Republished and modified from [308], with permission of © 1999 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

the pellets. Above 2 MPa, a thin layer of silicon grease was applied to the cylindrical part of the pellets. Similar curves were obtained for HNF mixed with 20% aluminum, 10% paraffin or 5% graphite. In addition to traditional regression rate measurements based on high-speed imagery with windowed bombs, an ultrasound regression rate analyzer has been evaluated, which is particularly useful for studying unsteady combustion that cannot be recognized in a constant volume bomb. An ultrasonic pulse is emitted into the burning pellet, reflected at the burning surface and the echo is recorded. A major restriction to the use of ultrasound in thick media is the attenuation. The attenuation and the speed of propagation of ultrasound in HNF pellets was therefore measured.

The HNF flame structure and decomposition gases were studied by UV and visible light absorption [250]. In addition to linear burn rate determinations in combustion bombs, planar laser-induced fluorescence was used to image the flame structures. The planar laser-induced fluorescence was used to establish concentration profiles of $\bullet\text{OH}$ and $\bullet\text{CN}$ radicals in the axial direction of the flame. This work showed that the decomposition and combustion of HNF is initiated by a proton transfer step. HNF combustion takes place in a narrow zone. Even at ambient pressure, most heat release occurs within the first millimeter of the flame. Although the chemical composition of HNF is very similar to that of nitramines and double-base propellants, the flame structure of HNF does not have a clear two-stage combustion zone. Most energy is released by reaction of NO_2 with other decomposition products. In a second stage the NO decomposes to O_2 and N_2 via slow, energetically neutral, reactions.

For combustion experiments, samples of HNF measuring 6 and 9 mm in diameter were pressed at pressures up to 236 MPa [210]. The density of these samples ranged from 93 to 96% of theoretical mean density. The samples had a smooth shiny surface. The value for friction sensitivity of pressed HNF is in the same range as what had been observed with crystalline HNF, but the drop height value for impact sensitivity has increased substantially (i.e., decreased sensitivity). Inserting microthermocouples into pressed HNF allowed the HNF temperature profile and surface temperature to be measured during burning. The surface temperature varied with pressure in the low-pressure range from 530 K at 0.1 MPa to 683 K at 1 MPa. These data agreed well with published data by Sinditskii et al. [268, 269, 309]. Sinditskii et al. [268] took thermocouple measurements at 0.04, 0.1, 0.5, 1, and 2 MPa. In the condensed phase, the temperature rose monotonically from the initial temperature to the melting point temperature (396 K). This region is followed by a melt/foam layer. At low pressures, this layer may be divided into two zones. In the first zone, the temperature increases slowly. For instance, at 0.1 MPa the temperature increases from 400 to ~ 425 K over the distance of 0.1 to 0.15 mm. In the zone of exothermic reaction the temperature increases more quickly. For example, at 0.1 MPa the temperature increases from 400 to 425 K at the solid boundary to 615 K over a distance of 0.15 mm. They measured a surface temperature 615 ± 11 K at 0.1 MPa and 698 ± 9 K at 1 MPa. At 2 MPa, they measured a surface temperature of 750 ± 10 K. Within 2 mm above the surface (at ambient pressures), the HNF

flame temperature was close to adiabatic. The temperature profiles in the gas phase showed two distinct flame zones. In the first flame, the temperature jumps from the surface temperature to 1320–1540 K, depending on pressure. This is followed by a dark zone, which is most often observed at 0.4 MPa but practically disappears at 2 MPa. After the dark zone, the temperature again begins to rise sharply to 2300–2720 K, which is just shy of the adiabatic flame temperature for HNF. It is assumed that 1.46 mol of NO per mol of HNF remain undecomposed in the equilibrium exhaust composition. It was theorized that decomposition of nitroform and oxidation of ammonia and carbon-containing intermediates (e.g., nitrile *N*-oxide CNO, or its isomer isocyanate free radical NCO) take place in the first flame zone. The second flame zone exothermicity may be due to decomposition of N_2O and NO. Emission spectroscopic measurements identified NO, O_2 , OH, NH, CN, and CH as major species in the flame, whereas absorption measurements indicated that the mol fraction of NO decreased away from the surface. Pressed neat HNF has a high burning rate with a burning rate exponent $n = 0.95$ for pressures below 2 MPa and $n = 0.85$ at pressures above 2 MPa up to 10 MPa [210]. Under similar conditions, Sinditskii et al. [291] reported $n = 0.92$ and 0.76, respectively. Differences between the Sinditskii data and those of other authors may be due to different methods of preparation of the strands. From the slope of the pressure vs reciprocal absolute temperature graph one can derive an enthalpy of sublimation of $156.5 \text{ kJ/mol} = 37.4 \text{ kcal/mol}$ for HNF.

A different burning rate measuring technique uses a sandwich of alternating layers of oxidizer and fuel. In one case, a layer of HNF can be sandwiched between two layers of combustible fuel (a solid propellant binder, e.g., GAP) and the diffusion flame structure can be observed [310]. The combustion of HNF takes place with a very short flame standoff, high rate of regression, high pressure exponent, and high monopropellant flame temperature compared with AP. Planar laser-induced fluorescence was used to study the structure of the flame in a sandwich arrangement with HNF and GAP. The flame structure is a combination of the HNF flame (a premixed flame) and a HNF/GAP flame (a diffusion flame). Small samples of neat HNF or sandwiches were ignited by zapping it with a pulse from a CO_2 laser in a high-pressure bomb with sapphire windows. OH or CN fragments were excited by shining a sheet of light across the flame in a direction perpendicular to the burning surface. Induced fluorescence was detected by a synchronized charge-coupled device camera and a filter perpendicular to the laser-illuminated sheet. Operating pressure was from 0.14 to 0.35 MPa. It was noticed that at higher pressures the area where no OH is seen is smaller and that the boundaries are sharper owing to the decreasing diffusion. It was concluded that the influence of the diffusion flame was extremely small. This matches with the observation that the burning rate of HNF-based propellants is essentially independent of the particle size. Figure 37 shows the burning rate of HNF/GAP propellants with coarse and fine HNF. For comparison, the burning rates of neat HNF and GAP are also shown.

Figure 37: Regression rate of hydrazinium nitroformate (HNF)/glycidyl azide polymer (GAP) propellants compared with that of neat HNF and GAP. (Reproduced and modified from [310]; Public domain.)

The methods of the study of solid propellant combustion include SEM analysis of quenched samples of partially burned propellant. Examining quenched samples of singed HNF at high magnification showed evidence for the formation of a foam layer [256, 311]. Measuring the bubble size and size distribution is an indication of the amount of gas evolving and bubbling to the surface before the sample was quenched. The thickness of the foam layer was dependent on the operating pressure (Figure 38).

Fourier transform infrared spectrometry and mass spectrometry of pyrolysis products can also provide details on intermediate species formation during decomposition and combustion. Attenuated total reflectance (ATR) spectra obtained by pressing the IR window against the quenched surface identified the residues on the surface. The difference between the spectra before and after burning and quenching is mainly due to the appearance of a small, new peak at 3450 cm^{-1} . Based on the analysis of the results, investigators identified probable overall reactions in the low pressure regime HNF decomposition around 0.1 MPa. It was found that decomposition of HNF takes place through the formation of ANF, and through dissociative vaporization. The gas phase near the surface of burning HNF may contain a large amount of hydrazine, ammonia and nitrogen dioxide (as decomposition products of nitroform). Nitrogen dioxide is subsequently reduced to molecular nitrogen in the secondary flame reactions. The primary reaction zone of the HNF flame is exchanging energy by radiative heat transfer with exothermic gas phase reactions of these fragments and fed by diffusional mass exchange from the subliming surface.

The effects of the additives, urea and ammonium metavanadate, on the HNF burning rate was studied in a chimney burner equipped with four polycarbonate windows. For high-pressure combustion, the chimney burner was pressurized with N_2 gas up to 10 MPa. The combustion process was recorded with a video camera through one of the windows. The video recordings were used to determine the burning rate of the pellets. Addition of 5% urea did not change the burning rate or burning rate curve slope of HNF significantly, whereas the NH_4VO_3 catalyst increased the burning rate of HNF pellets. The pressure exponent of a HNF/5% NH_4VO_3 pellet is 0.54 ± 0.02 , which is lower than 0.87 ± 0.01 found for a neat HNF pellet. However, ammonium metavanadate is not compatible with HNF and is not a practical choice.

The strand-burning rates of two different samples of HNF obtained from two different sources were very similar [312]. The strand-burning rates of HNF were compared with those of 3,6-bis(1H-1,2,3,4-tetrazol-5-amino)-2-tetrazine and di-amino-azo-tetrazine.

One of the concerns when formulating propellants with HNF is the high pressure exponent, which may lead to instability and runaway pressure spikes. Various burning rate modifying additives have been sought that would lower the pressure exponent to a safe level.

Instead of searching for burning rate modifiers to reduce the reaction order of the leading gas phase reactions in HNF deflagration, burning rate modifiers were sought enabling exothermic reactions in the upper layer of the solid phase. Recent data on decomposition and combustion suggest N_2H_4 , NH_3 , N_2O , and NO_2 to be present in the

solid phase. Planar laser-induced fluorescence experiments in the near surface region of burning HNF indicated that NO_2 is indeed present and reacting in the solid phase. Because of its high catalytic activity, finely powdered V_2O_5 was added to HNF, leading to an increase in burning rate by a factor of 11 with respect to neat HNF, at 0.1 MPa [292]. The pressure exponent was reduced to only 0.28, far below the target value of 0.5 required for practical application of HNF in propellant formulations. A handicap is that none of the catalysts tested so far is compatible with HNF.

3.4.2 Modeling of Strand-Burning Behavior of Hydrazinium Nitroformate

One rarely trusts a totally theoretical model to provide reliable data on the strand-burning rate of solid propellant ingredients. At best, models are used to extrapolate from experimental data to other temperature, density, and pressure regimes that were not yet experimentally covered. There are many models for the combustion of solid propellants and solid propellant ingredients, but not many models show good correlation with experimental data. One of the more recent models is the Ward-Son-Brewster (WSB) model developed at Los Alamos National Laboratory [313, 314]. This model can handle steady, unsteady, linear, and non-linear dynamic burning.

Because HNF burns so cleanly, it was chosen as a model substance for comparison of experimental and model prediction data. Although HNF has not yet been studied as exhaustively as AP, HMX, or AN, it was chosen for this comparison because there were several sets of recent experimental data available. First, the steady-state combustion of HNF was modeled using the WSB model [315, 316]. Burning rate, surface temperature and flame standoff all showed good agreement between theory and experiment for steady-state operation.

Other studies of HNF combustion used the $\alpha\beta\gamma$ model [317] for modeling unsteady combustion. The gas phase was treated in two ways: the classical high-activation-energy limit (Denison-Baum-Williams [DBW] model) and the low-activation-energy limit WSB model. Both limits allowed for an analytical solution of the gas-phase energy equation. The WSB approach was found to match the experimental observations much better than the DBW models for HMX and double-base propellants and it also gave good correlation for HNF. Assuming a condensed-phase activation energy of $E_c = 75 \text{ kJ/mol}$ was found to give good results in the whole pressure range of interest. This value is close to the 84 kJ/mol required to dissociate HNF into liquid hydrazine and nitroform.

Figure 39 shows the results of the calculated regression rate for both models, compared with experimental data taken from [301]. Like most energetic materials, the regression rate of HNF can be described by

$$r_b = ap^n.$$

The high-activation-energy limit yields the familiar $n = \delta/2 = 1$, whereas $n = 0.89$ was found experimentally for HNF combustion (least-squares fit to all data points). This pressure exponent is uncomfortably high.

Figure 39: Comparison of calculated and measured regression rate of neat hydrazinium nitroformate samples. (Reproduced and modified from [250], with permission from Dr. Jeroen Louwers, 27 May 2020.)

Later, the modeling was extended to include an advanced version of the WSB model that can handle unsteady and transient situations [318–320]. Combustion of HNF was modeled and the results were compared with experimental observations including steady regression rate (pressure, initial temperature, and radiant flux sensitivities), surface temperature, and linear frequency response to radiation. The results indicated that HNF combustion is overall slightly exothermic (increasing with pressure) with activation energies similar to that of proton transfer between hydrazinium and nitroformate ions. The gas-phase flame is highly exothermic with low activation energy, suggesting that the gas-phase reaction is more like a low-energy barrier (low E_g) chain-reaction process than a high-energy thermal process. This is similar to what has been suggested for nitrocellulose-nitroglycerin double-base propellants and for RDX. For both of these materials, and now for HNF, the low- E_g model has been shown to be in good agreement with experimental data for both steady and unsteady burning rate. The model also demonstrated the ability to capture the undesirable onset of non-linear combustion. In general, the calculated results exhibit motor behavior in agreement with that observed experimentally for different L^* -values at low pressures. As L^* increases from low, subcritical ($< L_o^*$) to high, supercritical ($> L_o^*$) values, burning rate and motor pressure go from erratic and/or oscillatory to steady and stable. Several non-linear combustion phenomena such as rapid initial (over-) pressurization, propellant extinction, chuffing, and dual-frequency and limit-cycle oscillations

that have been observed experimentally but which are beyond the capability of linearized models are also predicted. A rapid rate of initial pressurization can cause an ignition spike commonly attributed to erosive burning and/or igniter mass flux, but it may also be due to non-linear dynamic burning at low L^* . This pressure spike has been simulated for both high pressure-exponent homogeneous propellants and low pressure-exponent AP-composite propellants. A chuffing phenomenon (probably resulting from non-linear dynamic combustion) for HNF was predicted at low L^* . This is in contrast to the dynamic extinction phenomenon observed computationally for double-base propellants. The low gas-activation-energy WSB model was then used to model the non-linear unsteady combustion of energetic solids and additional validation of the model was obtained by modeling HNF combustion. Comparison of predictions for HNF combustion with a wide range of experimental observations including steady regression rate (pressure, temperature, and radiant flux sensitivities), surface temperature, and linear frequency response to radiation showed good agreement. Results indicated that HNF condensed-phase decomposition is overall slightly exothermic (increasing with pressure) with activation energies similar to those for proton transfer between hydrazinium and nitroformate ions. The gas-phase flame is highly exothermic with low activation energy, suggesting that the gas-phase process might be more like a low-energy barrier, chain-carrier process than a high-energy thermal process, similar to what has been suggested for nitrocellulose/nitroglycerin (NC/NG) and HMX.

A computer model was developed for the calculation of HNF flame temperatures and reactant concentration profiles [265, 321]. The dissociative evaporation of HNF according to

was analyzed on the basis of literature data on the thermal decomposition and combustion of HNF. The structure of HNF flames at 0.4, 1, and 5 atm was modeled by using data on the composition of products on the combustion surface that correspond to the reaction within the condensed phase and in agreement with chemical composition and enthalpy of formation of HNF. The gas-phase reaction of nitroform with hydrazine (and partially with ammonia) occurs in the flame zone at a higher temperature near 1300 K. Further increase of the temperature in the flame is due to the reactions in $\text{H}_2\text{O}/\text{N}_2/\text{N}_2\text{O}/\text{NH}_3/\text{NO}/\text{NO}_2/\text{HNO}_2/\text{CO}/\text{CO}_2/\text{HCNO}/\text{HCN}$ mixtures. The calculated results, illustrated in a series of graphs where the abscissa is the distance from the burning surface in millimeter, were then compared with published experimental data on the temperature and reactant concentration profiles of HNF flames. Figure 40 shows that the model predictions for flame temperature approximate experimental data points quite nicely. The two predicted temperature profiles 1 and 2 are for different kinetic factors, but both agree quite well.

In this work, the flame structure was modeled using a detailed kinetic mechanism containing 47 species: O, O_2 , H, H_2 , OH, H_2O , HO_2 , N, N_2 , N_2O , HNO, NH_3 , NH_2 , NO,

Figure 40: Measured (black dots) and predicted (1 and 2 lines) flame temperature profile above burning hydrazinium nitroformate at 5 atm. (Reprinted and modified from [265], with permission granted by Dr. Ermolin.)

NO_2 , N_2H , NH , N_2H_2 , H_2O_2 , HNO_2 , HNO_3 , NO_3 , H_2NO , N_2H_3 , N_2H_4 , CO , CO_2 , HCO , H_2CO , CN , HCN , HNC , CNO , NCO , NCN , C_2N_2 , HNCO , HOCN , HCNO , $\text{HC}(\text{NO}_2)_3$, $\text{HC}(\text{NO}_2)_2$, HCNO_2 , $\text{HC}(\text{O})\text{NO}_2$, $\text{C}(\text{NO}_2)_2\text{N}(\text{O})\text{OH}$, $\text{C}(\text{NO}_2)\text{N}(\text{O})\text{OH}$, $\text{C}(\text{NO}_2)\text{NO}$, and $\text{HC}(\text{O})\text{NO}$. It also contained 283 reversible reactions. Only monomolecular routes for the decomposition of nitroform and its fragments were considered. Except for the reaction

the rate constants of the reactions involving $\text{HC}(\text{NO}_2)_3$ and its fragments are unknown. The calculations were performed under the assumption that the rate-determining reaction of nitroform decomposition is the dissociation of nitroform

or its isomer

Increased computing power (even of desktop computers) has enabled significant advances in the modeling and numerical simulation of solid propellant combustion using simplified kinetics. For premixed, homogeneous energetic materials (called

“monopropellants”), a mathematical rigorous high activation energy condensed-phase decomposition model (high E_c) and low activation energy gas-phase reaction model (low E_g) gives significant improvement in predicting both steady and unsteady combustion [322]. The usefulness of that model was demonstrated for sample cases like the steady and unsteady combustion response of HNF, NC/NG, and HMX. For non-premixed, composite propellants, the laminate propellant configuration was used to refine modeling assumptions. See also [323].

3.4.3 Flame Structure and Temperature Profile of Burning Hydrazinium Nitroformate

The successful modification of combustion characteristics of HNF requires a better understanding of the combustion phenomenon, which can be achieved by a detailed study of the HNF combustion wave structure and its physicochemical processes. Specifically at low pressures (0.2 MPa), the combustion wave structure of HNF consists of different reaction zones, which interact by heat and mass transfer and not always in a steady-state manner.

Absorption experiments to resolve neat HNF flame structure at sub-atmospheric and elevated pressures (0.03–1 MPa) were carried out in a windowed bomb with sapphire windows [324, 325]. The obtained absorption spectra were used to determine NO concentration and NO temperature profiles above the surface. The NO reduction to N_2 and O_2 is slow. At ambient pressure the NO mol fraction decreased from 18% close above the burning surface to 10% at 9 mm above the surface. The HNF flame reached temperatures close to adiabatic near the burning surface. These high temperatures were reached with still considerable amounts of NO present (mol fraction 0.1). Following the combustion of HNF at low pressures, a yellow condensate was found in the windowed bomb. The absorption spectrum of a solution of this material was found to be similar to that of HNF so it must be sublimed HNF. This indicates that transition to the gas phase occurs by evaporation or by ejection of small particulates (or a combination of both).

Temperature profiles in the combustion wave of HNF were measured using fine tungsten/rhenium thermocouples, which were embedded in the HNF oxidizer pressed into quartz tubes with an internal diameter of 7 mm [326]. It was found that in the first zone the temperature rose from the surface temperature to the first flame temperature, which varies with pressure from 1320 to 1540 K. This zone was followed by a dark zone, which was most often observed on profiles at a pressure of 0.4 MPa and practically disappeared at 2 MPa. After the dark zone the temperature began to rise sharply to as high as 2300–2700 K.

Additional investigations of HNF monopropellant flames at low pressures were performed to estimate the global kinetic rates for the reactive gas-phase regions above the burning surface [256, 327, 328]. Laser Doppler anemometry (LDA) in conjunction with simultaneously recorded video images of the burning pellets have provided useful information on the flame structure of HNF oxidizer, such as the velocity profile

and the thickness of the two near-surface regions (the fizz zone and the dark zone). The global reaction rates and the overall reaction orders were determined from measurements of burning rate and flame zone thickness and their pressure dependence. The averaged gas velocity estimated from LDA velocity measurements, was used to determine the density of reacting gases in the fizz zone and dark zone.

An experimental investigation of the flame structure of HNF extended the range of experiments to pressures of 0.06 and 0.13 MPa [329]. Laser diagnostics, including LDA and coherent anti-Stokes Raman spectroscopy (CARS) techniques were used to obtain the gas velocity and temperature profiles above the burning surface of HNF pellets. Gas velocity and temperature in the flame regions close to the burning surface (primary reaction zone and non-luminous zone) was measured as a function of the distance to the condensed phase surface. The laser beams of the CARS system are much more intense than the laser beams of the LDA. Their intensity is so high that it can break the sapphire windows of the combustion chamber. Therefore, two of the sapphire windows were replaced with antireflection-coated BK7 laser windows. As a by-product of the LDA and CARS measurements, it was found that these flames contain dispersed two-phase regions with aerosols and gaseous reactants being irregularly released from bubbles formed at the foam layer. Aerosols larger than approximately 0.1–0.2 μm have been detected in the region between the foam layer and the primary reaction zone. At greater distances from the surface, the aerosols shrink to a size below 0.1 μm until they are fully consumed in the beginning of the brightly luminous flame. It appears that at a fixed location above the surface, one intermittently finds final products or gaseous reactants with the balance between the two shifting toward the hot products with increasing distance from the surface.

3.4.4 Surface Temperature of Burning Hydrazinium Nitroformate

For combustion experiments, samples of HNF pellets measuring 6 and 9 mm in diameter were pressed at pressures up to 236 MPa; the density of these samples ranged from 93 to 96% theoretical mean density. Figure 41 from Louwers [250] indicates a strong variation of surface temperature with combustion pressure in the low-pressure range from 530 K at 0.1 MPa to 683 K at 1 MPa. Under similar conditions, Sinditskii et al. [291] measured a surface temperatures 615 ± 11 K at 0.1 MPa and 698 ± 9 K at 1 MPa. At 2 MPa, they measured a surface temperature of 750 ± 10 K.

Spontaneous Raman spectroscopy was used to determine the temperature above the burning surface of HNF at 0.1 MPa [330]. These measurements showed a temperature of about 1800 K at 0.35 mm above the surface. At 1.2 mm above the surface, the N_2 contour was consistent with the adiabatic flame temperature (2766 K).

3.5 Safety Properties of Hydrazinium Nitroformate

The sensitivity data for crystalline HNF are summarized in Table 32.

Table 32: Sensitivity data for crystalline hydrazinium nitroformate.

Parameter	Units	Value
BAM Fallhammer	J	2–5
BAM Friction tester	N	12–36
Rotter impact tester	Figure of impact	33
R rotary friction tester	Figure of friction	1.3–1.5
Critical diameter	mm	10
Detonation velocity	km/s	8.2–8.5
UN 3(d) response to flame		passed
UN 4(b) 12-m drop test		passed
Electrostatic discharge	mJ	726–4500

BAM = Bundesanstalt für Materialforschung und Prüfung

Data source: [210]

Hydrazinium nitroformate as an unpackaged material is too friction sensitive at this point to meet the criteria from the United Nations (UN) Recommendations on the

Transport of Dangerous Goods. However, packaged in standard UN boxes, 4.5 kg of HNF passed the UN 4(b) 12-m drop test and, thus, can be transported as 1.1 D material.

During the development phase, samples of up to 333 g of HNF could be transported as a 1.4S class material in special *Explosafe* containers.

3.5.1 Drop Weight Impact Sensitivity of Hydrazinium Nitroformate

The drop weight impact sensitivity of HNF is 2.5 Nm [210].

3.5.2 Shock Sensitivity of Hydrazinium Nitroformate

Hydrazinium nitroformate detonates if initiated with a blasting cap. Dry HNF is more sensitive than AP and can be detonated by a detonator cap [214, 331].

3.5.3 Friction Sensitivity of Hydrazinium Nitroformate

When comparing HNF with ADN, the high friction sensitivity of dry HNF is often cited as a disadvantage and a matter of considerable concern. The friction sensitivity of HNF can be improved by co-crystallizing it with a stabilizer or by applying a coating. For instance, friction sensitivity of uncoated HNF in the BAM friction tester was 20 N, and for stabilized and coated HNF the number went up to 35 and 29 N respectively [210]. Other sources [245] reported a friction sensitivity of uncoated HNF of 12–16 N in the BAM friction tester.

Different grades of HNF were used by different laboratories in determining the sensitivity of HNF as summarized in Table 33. When comparing data, one must make sure that the information about the grade and pedigree of the material is carried along in the test report.

Table 33: Impact and friction sensitivity of hydrazinium nitroformate.

Sensitivity test	Apparatus	Result	Source
Impact sensitivity	BAM	3 J	van Zelst and van der Heijden [245]
Friction sensitivity load	BAM	16 N	
Impact sensitivity	BAM	2–5 J	Schöyer [210]
Friction sensitivity load	BAM	12–36 N	

BAM = Bundesanstalt für Materialprüfung

The friction sensitivity could be reduced significantly by phlegmatizing HNF with 9.8 to 20% paraffin wax. The load applied to the spinning disk to achieve ignition increased from 36 to 60 N before a reaction was observed.

3.5.4 Electrostatic Sensitivity of Hydrazinium Nitroformate

The electrostatic discharge sensitivity of HNF is 726 to 4500 mJ (50/50 no fire) (Louwers [250]; Schöyer [210]).

3.6 Toxicity of Hydrazinium Nitroformate

The lethal dose of HNF in rats is LD₅₀ 128 mg/kg body weight.

3.7 Applications of Hydrazinium Nitroformate

In a search for new storable and environmentally friendly high-performance solid propellants for the European Space Agency, HNF was identified as a very promising ingredient for a new generation of composite propellants. Two distinct advantages of HNF-based propellants over the current AP-based propellants are: **(1)** a very high specific impulse, which significantly increases the performance of the solid propellant and **(2)** chlorine-free exhaust products that prevent the formation of hydrochloric acid in the environment. In particular in the high atmosphere, chloride would promote ozone depletion.

3.7.1 Propellants with Hydrazinium Nitroformate.

Solid propellants with HNF, burning rates of propellants with HNF, and sandwich combustion experiments with HNF will be discussed in detail in future volumes in this series. There is some unavoidable overlap between these future three sections and the following section.

One of the earliest references to the use of HNF in solid propellants is in an evaluation of barrel-wear-reducing additives to gun propellants [332].

The promised increase in I_{sp} when using HNF-based propellants in comparison with state-of-the-art AP-based solid propellants is 2 to 7%. The main incentive in switching from AP to HNF as the oxidizer in solid propellants is the chlorine-free exhaust resulting in less air pollution at the start sites and a reduction of the ozone depletion potential in the stratosphere. The other advantage is that HNF is not as persistent as perchlorate ion and does not accumulate in the ground water if it is spilled accidentally. Similar improvements could be achieved with ANF, but it is not as energetic and not as stable as HNF.

Several survey papers were published that primarily deal with the formulation of HNF-based solid propellants, but also provide additional information about the production of HNF and its competitive position in comparison with other oxidizers. Among the new oxidizers vying to replace AP and create a more environmentally friendly propellant, ADN and HNF compete for the favorite spot. Several studies

have compared the advantages and disadvantages of ADN and HNF and some have prepared propellants under identical conditions for side-by-side evaluation. See also [333]. Coating HNF granules with a binder that is a Lewis acid, e.g., a boron-organic polymer, can stabilize and desensitize the solid propellant [334].

3.7.2 Monopropellants with Hydrazinium Nitroformate

An early patent described mixtures of dinitromethane (which is not very stable) or trinitromethane with hydrazine or UDMH as monopropellants [335]. Later studies on the use of HNF in monopropellants were conducted mostly in Europe under ESA sponsorship. The results will be discussed in *Encyclopedia of Monopropellants*. If applications for HNF can be found both in solid propellants and in monopropellants, the increased demand might encourage industry to establish a broader supply base for this energetic chemical.

3.8 Other Nitroformate Salts

After the success with HNF, it was logical to look for properties of salts formed from other high-nitrogen bases with nitroform as the acid. These salts can be prepared either directly from the base and trinitromethane or by substitution of the cation in ANF or HNF. These salts are discussed in other chapters of this book. Ammonium nitroformate is discussed in *Encyclopedia of Oxidizers*, chapter “Dinitramide Oxidizers,” immediately following the chapters on ADN, and contains the nitro groups in the anion attached to nitrogen instead of carbon, so that the two salts have some structural similarity and are discussed next to each other. Several specific nitroformate salts of organic amines are listed in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines,” following the description of their parent amines. Other applications will be contained in future more general chapters on high nitrogen compounds as additives to solid propellants, gun propellants, and gas generants.

Here are two good papers by Göbel and Klapötke describing a wide range of nitrogen-rich nitroformate salts, including ANF and HNF [260, 336].

Two derivatives of HNF, namely monomethylhydrazinium nitroformate and dimethylhydrazinium nitroformate, were synthesized and suggested to be promising new, less sensitive high-performance energetic materials [287]. Nitroformate salts of 4-amino-1,2,4-triazole and 3,6-diguanidino-1,2,4,5-tetrazole would make good high-nitrogen additives [337].

Methylhydrazinium nitroformate was prepared and its crystal structure was examined by XRD, NMR, Raman and IR spectroscopy and the enthalpies of formation predicted by computational chemistry [338].

The thermal stability and decomposition kinetics of potassium nitroformate (KNF) was investigated by DSC and TGA/DTA to obtain information on safety for handling,

storage, and use [339]. The main thermal degradation for KNF occurs during two temperature ranges of 543–603 K (270–330) and 633–703 K (360–430 °C). Crystallized KNF dehydrated (at about 381 K = 108 °C) before its decomposition.

Potassium nitroformate is not likely to find its way as a rocket propellant, but it is a useful intermediate in the synthesis of more complex molecules that carry the trinitromethyl group. The reaction mechanism of the thermal decomposition of KNF has been investigated by density functional theory [340]. The geometric structures of reactants, intermediates, transition states, and products were fully optimized. There are four feasible reaction pathways. The energy barrier of the rate-limiting step is 216.30 kJ/mol. The dominant products predicted theoretically were KNO_2 , NO_2 , NO , and CO , which is in agreement with experiments.

4 Hydrazinium Dinitramide

Hydrazinium(1+) dinitramide, $[\text{N}_2\text{H}_5][\text{N}(\text{NO}_2)_2]$, $\text{N}_5\text{H}_5\text{O}_4$, HDN, CAS RN [165603-97-4], is an energetic salt that has not yet been as thoroughly investigated as ADN.

4.1 Physical Properties of Hydrazinium Dinitramide

4.1.1 Melting Point and Phase Diagrams of Hydrazinium Dinitramide

The melting point of HDN is 353–355 K (80–82 °C) [10], lower than that of ADN, which melts at 365.6 K (92.44 °C). Other sources reported that HDN exists in the crystalline state under normal pressure conditions with a melting point of 356 K (83 °C).

4.1.2 Density and Partial Molar Volumina of Hydrazinium Dinitramide

A summary of literature data on the density of HDN is given in Table 34.

Table 34: Density of hydrazinium dinitramide.

Density, g/cm ³	Method	References
1.83	X-ray	Schmitt, Bottaro, and Penwell [341]
1.848	X-ray	Gilardi and Butcher [66]

4.1.3 Thermodynamic Properties of Hydrazinium Dinitramide

4.1.3.1 Enthalpy of Formation and Heat of Combustion of Hydrazinium Dinitramide

The heat of combustion of HDN in a calorimetric constant volume bomb is $\Delta U_{\text{B}} = -5109 \pm 7.1 \text{ J/g}$ ($-1221 \pm 1.7 \text{ cal/g}$) in comparison with that of ADN, which is $\Delta U_{\text{B}} =$

$-3592 \pm 6.3 \text{ J/g}$ ($-858.48 \pm 1.5 \text{ cal/g}$) [10]. From this number, the enthalpy of formation of the two salts can be calculated, which turns out to be $-13.64 \pm 1.2 \text{ kJ/mol}$ ($-3.26 \pm 0.28 \text{ kcal/mol}$) for HDN and $-134.6 \pm 0.5 \text{ J/g}$ ($-32.16 \pm 0.11 \text{ kcal/mol}$) for ADN. The enthalpy of formation of HN determined under the same conditions was $-246.2 \pm 0.96 \text{ kJ/mol}$ ($-58.86 \pm 0.23 \text{ kcal/mol}$). The enthalpy of formation of HDN ($-13.6 \text{ kJ/mol} = -3.26 \text{ kcal/mol}$) is much less negative than that of ADN ($-134.6 \text{ kJ/mol} = -32.16 \text{ kcal/mol}$), which may lead to better rocket propellant performance. Table 35 gives a summary of the enthalpy of formation data for HDN.

Table 35: Enthalpy of formation data for hydrazinium dinitramide.

Enthalpy of formation		Method	Authors	Year	References
kJ/mol	kcal/mol				
-33.5	-8	Calculated	Schmitt, Bottaro and Penwell	1993	[341]
-13.64 ± 1.17	-3.26 ± 0.28	Measured, calorimetric	Konkova et al.	2009	[10]

See also [342].

4.1.3.2 Heat of Solution and Dissociation of Hydrazinium Dinitramide

The enthalpy of solution of HDN in water at infinite dilution is $47.32 \pm 0.08 \text{ kJ/mol}$ ($11.31 \pm 0.02 \text{ kcal/mol}$), in comparison with that of HN, which is 37.95 kJ/mol (9.07 kcal/mol) and that of ADN, which is 36.44 kJ/mol (8.71 kcal/mol) [10].

4.1.4 Optical Properties of Hydrazinium Dinitramide

4.1.4.1 Infrared Spectra of Hydrazinium Dinitramide

Predicted IR spectra in the gas phase and in solution were obtained from quantum mechanical calculations [343]. There were four characteristic regions in the simulated spectra: The frequencies near 3426 cm^{-1} in the gas phase and 3353 cm^{-1} in solution are caused by N—H stretching vibrations. The strongest peak, which appeared at 2462 cm^{-1} in the gas phase (2786 cm^{-1} in solution), was attributed to the vibration of protons between the two fragments of HDN. The frequencies at about 1625 and 1220 cm^{-1} in the gas phase were attributed to symmetrical and asymmetrical N=O stretches. The frequency at about 876 cm^{-1} in the gas phase was assigned to the asymmetrical $\text{O}_2\text{N—N—NO}_2$ stretching vibration and a shoulder owing to the $\text{O}_2\text{N—N—NO}_2$ symmetrical stretching vibration appears in solution. The frequencies below 800 cm^{-1} were mainly associated with in-plane and out-of-plane stretches of $\text{O}_2\text{N—N—NO}_2$ and the shear swing of N—H. The calculated IR spectra in the gas phase and in solution were quite different because of their differences in conformation and environment.

4.1.4.2 Ultraviolet Spectra of Hydrazinium Dinitramide

The UV spectrum that arises from the transition of the valence electron can provide useful information, such as quantitative or qualitative analysis and simple structural analysis. Calculations predicted a strongest peak at 253 nm, which comprised several excitations. The electron transitions happened inside the $\text{N}(\text{NO}_2)_2^-$ anion.

4.1.5 Molecular Structure of Hydrazinium(1+) Dinitramide

Hydrazinium(1+) dinitramide, $[\text{N}_2\text{H}_5]^+ [\text{N}_3\text{O}_4]^-$, is a very energetic, but also very sensitive high-energy density material. Its crystal structure was examined as part of a series of publications on a new class of flexible ion energetic salts [66]. Hydrazinium(1+) dinitramide crystallizes in the monoclinic space group $P2_1/c$ with cell dimensions $a = 8.312(3) \text{ \AA}$, $b = 5.654(1) \text{ \AA}$, $c = 10.659(3) \text{ \AA}$, $\beta = 93.73(3)^\circ$, $Z = 4$, $\rho_c = 1.848 \text{ g/cm}^3$. See also Table 14. The structure of HDN in the solid state contains cations and anions that are linked by hydrogen bonds. The structure contains protonated amine cations and dinitramide anions linked by hydrogen bonding and provides a constrained local environment for the dinitramide anions owing to extensive hydrogen bonding. Atomic coordinates, bond lengths and angles, and equivalent isotropic displacement parameters for the salts were calculated and tabulated. The molecular structure of isolated ions of HDN is illustrated in Figure 42.

Figure 42: Molecular structure of hydrazinium dinitramide

The structures of HDN in the gas phase and in aqueous solution have been studied by using quantum chemical calculations at different levels of theory [343]. The intramolecular hydrogen bond interactions in HDN were studied in comparison with those in ADN, HNF, and ANF. The calculation showed that HDN possessed the strongest hydrogen bonds, with the largest hydrogen bond energy ($-47.95 \text{ kJ/mol} = -11.46 \text{ kcal/mol}$) and the largest total hydrogen bond energy ($-60.29 \text{ kJ/mol} = -14.41 \text{ kcal/mol}$). The charge transfer between the cation and the anion, the binding energy, the energy difference between the frontier orbitals and the second-order perturbation energy of HDN were all largest among the four investigated compounds. These strongest intramolecular interactions accounted for the highest onset of decomposition temperature of HDN among all four compounds. A calculation of the

binding energies of HDN and ADN with water molecules (-70.16 kJ/mol for HDN and -73.24 kJ/mol for ADN) demonstrated that ADN had a stronger ability to absorb water molecules than HDN, i.e., it is more hygroscopic.

4.2 Thermal Stability of Hydrazinium Dinitramide

Hydrazinium dinitramide has inadequate thermal stability to make it a useful rocket propellant ingredient. The DSC thermogram of HDN is shown in Figure 43, from Schmitt et al. [341]. See also [344].

Figure 43: Thermogram of hydrazinium dinitramide decomposition. (Reproduced and modified from [341].)

4.3 Explosive and Fire Hazards of Hydrazinium Dinitramide

Hydrazinium dinitramide is highly shock (impact) sensitive and thus has no practical value [341]. Additionally, as observed in DSC, the melting point is slightly lower than that of the ammonium derivative, further reducing the possibility of this compound having practical value as a solid compound. It is quite soluble in water, so it could be used to formulate monopropellants similar to those derived from ADN.

The predicted detonation velocity ($D = 8.34$ km/s) and detonation pressure ($P = 30.18$ GPa) of HDN were both higher than those of ADN ($D = 7.55$ km/s and $P = 24.83$ GPa) [343].

5 Hydrazinium Azide

Hydrazinium azide, also known as N_5H_5 , $N_2H_5N_3$, $[N_2H_5^+][N_3^-]$, HA, HAZ, hydrazine azide, hydrazine trinitride, CAS RN [14662-04-5], is not an oxidizer, but it is a very energetic compound and we opted to list it here immediately following the other hydrazinium salts that are true oxidizers. It is the compound with the highest nitrogen content (93 mass-%).

There are two different Chemical Abstract Service Registry Numbers listed for HA: [38551-29-0] and [14662-04-5]. It is not known which is the correct (preferred) one. There is a different CAS RN for hydrazinium(1+) azide hydrazinate, which is [14546-45-3].

Hydrazinium azide, $N_2H_5N_3$, is closely related to another hydronitrogen, ammonium azide, NH_4N_3 , which is described in *Encyclopedia of Liquid Fuels*, chapter “Azido Compounds,” along with organic azido compounds. That is not a very logic location for an ionic azide compound such as ammonium azide, but it had to be either spliced in with ammonium salt oxidizers such as AN or AP, or listed here, close to the HA section.

5.1 Preparation of Hydrazinium Azide

Whereas most other acids used in the preparation of hydrazinium salts are readily available, hydrazoic acid HN_3 is not readily available because it is unstable and explosive; moreover, it must be prepared fresh and handled (in solution) with extreme care if used in the preparation of HA. The preparation of HN_3 by acidifying azide salts and driving the diluted HN_3 vapor with an inert diluent gas into a quantity of hydrazine contained in a receiving flask has been practiced, but this is an extremely hazardous operation [345].

A safer and cleaner method is the preparation of hydrazoic acid by passing a solution of sodium azide through a H^+ -charged cation exchange resin, followed by distillation (again with an inert carrier gas) into a hydrazine sorbent solution. A dilute solution of hydrazoic acid can be prepared by ion exchange and then neutralized with hydrazine hydrate [346–348]. Crystals of HA obtained from a concentrated aqueous solution can then be filtered off and dried over P_2O_5 in a desiccator.

Hydrazinium azide can also be prepared by treatment of ammonium azide with hydrazine or by reacting a solution of AH in ethanol with an ethereal solution of hydrogen azide [349]. The chemistries of hydrazine and hydrogen azide are closely related, and it is quite feasible that HA is formed during partial oxidation of hydrazine or decomposition of hydrazinium(1+) nitrate solutions:

Hydrazinium azide can be prepared by reaction of sodium azide and hydrazinium(2+) sulfate, but half of the azide is lost as hydrogen azide [350]:

This reaction is carried out by using finely pulverized starting materials in refluxing *n*-butanol as a solvent. The sodium sulfate is insoluble in butanol, but HA is slightly soluble and precipitates after decanting the hot solution from undissolved sodium azide and cooling. Reported yields range from 37 to 70% of theoretical yield. A similar method was developed by Thiokol RMD, using methanol instead of butanol. One can make better use of the azide by reacting sodium azide with hydrazinium(2+) sulfate and additional hydrazine (hydrate) or by using the dihydrazinium(1+) sulfate:

The reaction is carried out in ethanol or isopropanol as the solvent, in which the sodium sulfate is insoluble and can be separated from the alcoholic HA solution [351].

Hydrazinium azide can be synthesized by bubbling nitrogen-diluted gaseous hydrogen azide, made from stearic acid and sodium azide at 403 K (130 °C), into an ice-salt-cooled ethanolic solution of hydrazine hydrate. The crude colorless salt can be recrystallized in absolute methanol to obtain crystals with a melting point of 345 K (72 °C) [352, 353]. The same method can also be used to prepare the azides of methylhydrazine, 1,1-dimethylhydrazine, phenylhydrazine, and acethydrazide [354–357]. As more methyl groups are attached to hydrazine, the melting point of the azide salt decreases. The volatility of the compound increases. With more methyl groups on the nitrogen base, the elimination of HN_3 from the molecule by dissociation gets easier.

Hydrazinium(1+) azide can be prepared by reaction of trimethylsilyl azide with hydrazinium(1+) fluoride in methanol [358]:

The same method can also be used for preparation of ammonium azide or hydroxylammonium azide.

A HA hydrazinate $\text{N}_2\text{H}_5\text{N}_3 \cdot \text{N}_2\text{H}_4$ was obtained by Dresser, Browne, and Mason [349] by treatment of a nearly saturated solution of HA in AH with an equal volume of ethanol. The precipitate of white crystals was dried over sulfuric acid and had to be stored in a desiccator over calcium chloride under nitrogen. The hydrazinate is very deliquescent and melts at 339.5 K.

A double salt of HA and triaminoguanidinium azide is obtained from triaminoguanidine, sodium azide, and hydrazinium sulfate by refluxing in methanol [359]. After filtering off the insoluble sodium sulfate, the product can be crystallized from methanol. It has a formula $\text{CH}_{14}\text{N}_{14}$, a molecular weight of 222.2 g/mol, a standard heat of formation $(\Delta H)_f^{298} = +664.8 \text{ kJ/mol}$ (+158.9 kcal/mol), and de-

composes at 423 K (150 °C). The high nitrogen content (88% by weight) would make this compound a valuable ingredient for low-temperature, nitrogen-producing solid propellants, but the volatility prohibits any such use. The propellant would have to be stored in the refrigerator all the time.

5.2 Physical Properties of Hydrazinium Azide

The melting point of anhydrous, hydrazine-free HA was reported to be 343.6 K (70.5 °C). Discrepancies in the melting point of HA reported a few decades ago, in 1979, melting point = 355 K = 82 °C [15] and 1972, melting point = 343.6 K = 70.5 °C [360] and those reported by earlier investigators (year 1969), melting point = 347.6 K = 74.5 °C; year 1933, melting point = 347.6 K = 74.5 °C [349] are most likely caused by varying amounts of excess hydrazine tenaciously adhering to the crystalline salt samples. HA prepared by reaction of trimethylsilyl azide with hydrazinium(1+) fluoride in methanol had a melting point of 348 K (75 °C) [358].

5.2.1 Melting Points of Systems with Hydrazinium Azide

The question arose if solutions of hydrazinium salts in water or hydrazine should be dealt with here under hydrazinium salts or in the chapter on their parent base, hydrazine. Although these solutions are not solid, they are discussed here along with the properties of these salts before they were dissolved in a solvent. The binary system hydrazine/HA has been investigated repeatedly since the beginning of the twentieth century. Dresser, Browne, and Mason reported a eutectic mixture melting at 255.6 K and containing 77% N_2H_4 [349]. The melting temperature rises very steeply on the HA-rich side of the eutectic points (Figure 44).

Kahrs and Seamans found a minimum melting composition at 258 K that contained 76.2% N_2H_4 [351, 361]. Finally, Pannetier and Margineanu [360] arrived at a melting point of 257 K with a mixture containing 76.3% hydrazine. These variations in melting point were most likely caused by unrecognized traces of water in the mixtures. The ternary system $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{N}_3/\text{H}_2\text{O}$ has been investigated for four hydrazine-water solvents initially containing 85.2, 90.5, 95.9, and 98.8% N_2H_4 . The HA content in the ternary mixture was varied from 0 to 50 mass-% $\text{N}_2\text{H}_5\text{N}_3$. The small number of data points along the $\text{N}_2\text{H}_4 - \text{H}_2\text{O}$ axis of the system did not allow construction of a complete ternary diagram (Figure 45). Compositions with higher water content (higher than 15%) are of less practical interest because the specific impulse of such ternary mixtures when used as monopropellants begins to suffer.

Hydrazinium azide hydrazinate is less hygroscopic and less volatile than HA itself. In DSC with hermetically sealed sample pans, two endothermic phase transitions were observed. Melting without decomposition occurred at 338 K (65 °C), and with de-

Figure 44: Freezing point diagram for the hydrazine/hydrazinium azide system. (Reprinted and modified from [349], with permission from © 1933 American Chemical Society.)

Figure 45: Freezing point diagram of ternary hydrazine/hydrazinium azide/water mixtures. (Reproduced and modified from [347] as shown in [2].)

composition at 424 K (151 °C). Explosion of $[\text{N}_2\text{H}_5]^+[\text{N}_3]^- \bullet \text{N}_2\text{H}_4$ yielded dinitrogen, ammonia, and dihydrogen. Compared with HA, the hydrazine adduct produced larger amounts of ammonia in the explosion. See also [345, 346].

5.2.2 Density of Hydrazinium Azide

Data for the density of crystalline HA are summarized in Table 36.

Table 36: Density of hydrazinium azide.

Density, g/cm ³	Method	Authors	References
1.40	pycnometric	Yakovleva, Kurbangalina, and Stesik 1974	[117]
1.407	XRD	Chiglien et al. 1974	[69]
1.400	XRD	Pannetier et al. 1972	[70]
1.419	XRD	Zhao et al. 2019	[358]

XRD = X-ray diffraction

A mixture of 24% HA, 1% water, and 75% hydrazine had a density of 1.104 g/cm³. A similar mix consisting of 19% HA, 4.5% water, and 76.5% hydrazine had a density of 1.087 g/cm³ [362]. The density of binary $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{N}_3$ and ternary $\text{N}_2\text{H}_4/\text{N}_2\text{H}_5\text{N}_3/\text{H}_2\text{O}$ mixtures can be calculated by using the equations summarized in Table 37.

^c T = temperature, K

5.2.3 Solubility of Hydrazinium Azide

Hydrazinium azide is very hygroscopic and it is difficult to obtain an absolutely water-free sample for determination of its physical properties. It is best to avoid the use of water as a solvent if one wants to obtain a truly water-free salt. HA can be re-crystallized from methanol or ethanol in which it is quite soluble (Table 38).

Table 38: Solubility of hydrazinium azide in non-aqueous solvents.

5.2.4 Optical Properties of Hydrazinium Azide

The IR spectrum of HA is shown in Figure 46.

Figure 46: Infrared spectrum of hydrazinium azide. (Reproduced and modified from [13, 111])

Absorption bands of the hydrazinium ion in hydrazinium(1+) azide are very similar to those in hydrazinium halogenides. Absorption at 2036, 645, and 636 cm^{-1} stems from the azide ion [70, 354]. The sharp peak at 2034 cm^{-1} is the dominating feature of the spectrum (Figure 47).

Absorptions in the IR spectrum of hydrazinium(1+) azide prepared from trimethylsilyl azide and hydrazinium fluoride, crystals embedded in a KBr pellet, were at 3356, 3285, 3053, 2033, 1598, 1508, 1338, 1234, 1094, 953, 649, 643, and 460 cm^{-1} [358].

Figure 47: Infrared spectrum of hydrazinium azide. (Reproduced and modified from [354], with permission from Professor T. M. Klapötke.)

5.2.5 Molecular Structure of Hydrazinium Azide

The crystal structure of HA was already listed in Table 14 along with the crystal structure of other hydrazinium salts. $\text{N}_2\text{H}_5\text{N}_3$ is a monoclinic structure with the structural parameters $a = 5.663(2) \text{ \AA}$, $b = 12.436(3) \text{ \AA}$, $c = 5.506(2) \text{ \AA}$, and $\gamma = 114.0(1)^\circ$.

The structural parameters of monoclinic HA crystals with a space group of $P2_1/n$ obtained by crystallographic XRD measurements are $a = 5.641(2) \text{ \AA}$, $b = 5.521(2) \text{ \AA}$, $c = 11.306(4) \text{ \AA}$, $\alpha = \gamma = 90^\circ$, $\beta = 93.261(4)^\circ$, $Z = 4$ [358]. The calculated crystal density was 1.419 g/cm^3 .

The data for the crystal structure of HA were already listed in Table 14 above. HA crystallizes as the monohydrazinate, with an extra molecule of hydrazine as a ligand in the hydration sphere of the ions. HA hydrazinate, $[\text{N}_2\text{H}_5]^+[\text{N}_3]^- \cdot \text{N}_2\text{H}_4$ was synthesized from equimolar amounts of HA and hydrazine and characterized by single crystal XRD: monoclinic, space group $P2_1/c$, $a = 6.3704(2) \text{ \AA}$, $b = 12.1111(4) \text{ \AA}$, $c = 6.9940(2) \text{ \AA}$, $\beta = 91.8666(2)^\circ$, $V = 539.32(3) \text{ \AA}^3$, $Z = 4$, $\rho = 1.320 \text{ g/cm}^3$ [352, 353].

The structural, elastic, mechanical, electronic properties, formation energy, and cohesive energy of orthorhombic NH_4N_3 and monoclinic $\text{N}_2\text{H}_5\text{N}_3$ crystals were calculated by the plane-wave method based on the first-principles density functional theory [363]. The calculated results of the two compounds were in agreement with previously published values. The orthorhombic NH_4N_3 is more energetically stable than $\text{N}_2\text{H}_5\text{N}_3$. The independent elastic constants, bulk modulus, shear modulus, Young's modulus, and Poisson's ratio of the two compounds were investigated. The electronic band structures, density of states and charge density distributions of orthorhombic NH_4N_3 and monoclinic $\text{N}_2\text{H}_5\text{N}_3$ were analyzed so as to better understand electronic properties and chemical bonding in these compounds.

Structural, elastic, mechanical, and electronic properties of monoclinic $\text{N}_2\text{H}_5\text{N}_3$ at ambient and very high pressure were investigated using a plane-wave ultrasoft pseudopotential method within the density functional theory [364]. Calculations of the

pressure dependencies of structural parameters, elastic constants, mechanical properties, band gaps, and density of states of monoclinic $\text{N}_2\text{H}_5\text{N}_3$ showed that monoclinic $\text{N}_2\text{H}_5\text{N}_3$ is unstable at pressures exceeding the value 126.1 GPa. Monoclinic $\text{N}_2\text{H}_5\text{N}_3$ was predicted to behave in a ductile manner in the pressure range from 0 to 200 GPa. $\text{N}_2\text{H}_5\text{N}_3$ is a monoclinic structure with the structural parameters $a = 5.663(2) \text{ \AA}$, $b = 12.436(3) \text{ \AA}$, $c = 5.506(2) \text{ \AA}$, and $\gamma = 114.0(1)^\circ$. The density functional theory calculations predicted the following structural parameters: $a = 5.9846 \text{ \AA}$, $b = 12.1388 \text{ \AA}$, $c = 5.5580 \text{ \AA}$, and $\gamma = 117.921^\circ$. A comparison showed that the parameters a , c , and γ were overestimated, but b was underestimated.

The transformation of HA to molecular N_8 has been investigated at high pressures up to 68 GPa using confocal micro-Raman spectroscopy and synchrotron powder XRD [365]. The results showed that HA undergoes structural phase transitions from solid HA-I to HA-II at 13 GPa, associated with the strengthening of hydrogen bonding, and then to N_8 at 40 GPa. The transformation of HA to the recently predicted N_8 ($\text{N} \equiv \text{N}^+ - \text{N}^- - \text{N} = \text{N} - \text{N}^- - \text{N}^+ \equiv \text{N}$) is evident by the emergence of new peaks at 2384, 1665, and 1165 cm^{-1} , arising from the terminal N—N stretching, the central $\text{N} = \text{N}$ stretching, and the N—N stretching respectively. However, upon decompression, N_8 decomposed to $\epsilon\text{-N}_2$ below 25 GPa, but the remnant can be seen at pressures as low as 3 GPa.

5.2.6 Thermodynamic Properties of Hydrazinium Azide

Thermodynamic properties of HA are summarized in Table 39.

Table 39: Thermodynamic properties of hydrazinium azide.

5.3 Chemical Properties of Hydrazinium Azide

5.3.1 Reactions of Hydrazinium Azide

The reaction of HA with sulfuric acid released hydrogen azide and formed hydrazinium(2+) sulfate, which was identified by its crystal structure [368].

Hydrazinium azide forms a 1 : 1 solvate with hydrazine.

5.3.2 Thermal Stability of Hydrazinium Azide

In DTA, HA melts at 355 K and begins to decompose at 446 K [15, 369]. HA may undergo a phase transition above room temperature [354]. Figure 48 shows a thermogram of HA in a pierced aluminum tube measured by DSC. The peaks before the melting point (339.0 K = 65.9 °C) could not be identified and may be due to adsorbed moisture or free hydrazine as a solvate. The DSC thermogram in Figure 48 shows that HA that was stored in an desiccator behaves differently from what one would expect from the TGA experiment.

Figure 48: Differential scanning calorimetry thermogram of hydrazinium azide at a heating rate of 5 °C/min. (Reproduced and modified from [354], with permission from Professor T. M. Klapötke.)

The DSC thermogram of a sample of HA prepared from trimethylsilyl azide and hydrazinium fluoride showed only a melting endotherm at 348.8 K (75.66 °C) and a subliming endotherm at 448.7 K (175.57 °C) (Figure 49).

Figure 49: Differential scanning calorimetry thermogram of hydrazinium azide at a heating rate of 5 °C/min. (Reprinted and modified from [358], with permission from © 2019 American Chemical Society; permission conveyed through RightsLink.)

5.4 Strand Burning of Hydrazinium Azide

The steady-state unoxidized combustion of ammonium azide and hydrazinium(1+) azide at pressures from 0.1 to 36 MPa was studied in a windowed bomb [370]. Hydrazinium(1+) azide burned 3–4 times faster than ammonium azide over the entire pressure range. The combustion temperature of both compounds was 240–430 K higher than the temperature calculated for the thermodynamic equilibrium composition of the combustion products due to the presence of large amounts of undissociated NH_3 (0.97 and 0.87 mol-% per mol of NH_4N_3 and $\text{N}_2\text{H}_5\text{N}_3$ respectively). The reaction at the combustion surface was the dissociation of the salts into HN_3 and the parent base. The azide salts are very volatile and dissociate into free hydrazoic acid and the parent base prior to burning.

Hydrazinium azide can be used in solid propellants with boron compounds [371] or in gas dynamic laser gas generants [372]. Monopropellants containing HA will be described in *Encyclopedia of Monopropellants*.

5.5 Explosive and Fire Hazards of Hydrazinium Azide

In the BAM drop hammer apparatus, the lower threshold of initiation was 40 Nm, which is not very sensitive [354]. In the BAM friction test apparatus, the onset of reaction was at a piston load of 80 N. In the electrostatic-sensitivity test apparatus, a discharge of 32 J did not initiate an explosion.

Hydrazinium azide is one of the more energetic hydrazine salts that may not only decompose but also detonate when heated. The drop-weight sensitivity number of HA was lower (i.e., it was more sensitive, easier to initiate) than that of tetryl, in the range 10 kg × 25 cm. The first experiments showed that the dry salt can detonate under both low- and high-velocity conditions [373]. To obtain more reproducible results, investigators used charge diameters that were at least five to six times greater than the critical diameter for stable detonation [117]. The single crystal density of HA is 1.4 g/cm³. The critical diameter depends on the bulk density of the sample and increases with bulk density from 4 mm at 0.6 g/cm³ to 20 mm at 1.2 g/cm³. Dependence on this form is typical for explosives with a low heat of reaction, such as ammonium nitrate. It is thought to be caused by slowing down the dissociation of the salt into an acid and a base, which precedes decomposition. The detonation velocity of low-density (0.68-g/cm³) charges increased with charge diameter and leveled off at 4950 m/s at 20 mm, which is five critical diameters. Using steel and glass casings for confinement and charges 20 mm in diameter, the dependence of detonation velocity on charge density was also determined. The detonation velocity increased from 2500 m/s at very low densities to 7000 m/s at 1.2 g/cm³. Under most conditions of confinement and sample diameter, the detonation velocity decreased when the density was increased beyond 1.2 g/cm³. This type of maximum had also been observed with ammonium azide. In the linear slope of the curve, the dependence of detonation velocity on density can be described by the equation

$$D = 1.80 + 4.60\rho$$

where ρ is entered in g/cm³ and D is the detonation velocity in km/s. The detonation velocity of HA exceeds even that of powerful explosives, such as hexogen or PETN, in spite of the fact that its heat of explosion is less than that of hexogen or PETN. Its detonation velocity is even higher than that of solid HN [113]. In spite of this higher detonation velocity, HA will not become an industrial explosive because it is very difficult to prepare and because it is so hygroscopic.

6 Other Hydrazinium and Nitrohydrazinate Salts

The discovery of the dinitramidic acid and its salts has given great impetus to the search for similar energetic nitrogen compounds containing N—NO₂ groups suitable as oxidizers in solid propellants. Replacing one hydrogen on ammonia with a nitro group has led to nitramine; replacing two nitro groups on ammonia has led to dinitramidic acid. Can the same substitution be made with hydrazine? These compounds may not be stable, but at least on paper (or on the screen of the computer) they can be looked at. The remaining hydrogen on a nitrogen or carbon atom adjacent to a nitro group becomes quite acidic owing to the drain of electrons toward the electrophilic nitro group. So nitrohydrazine and 1,2-dinitrohydrazine should be acids similar to dinitramidic acid, forming nitrohydrazinate salts. Sometimes the salts are more stable than the parent acid.

It is known that the reaction of N₂H₄ with NO₂ or N₂O₄ is one of the most vigorous hypergolic reactions. Obviously that is not a good way to replace hydrogen atoms on the N₂H₄ molecule with —NO₂ groups in an effort to synthesize high-energy compounds. Two chlorine-free but oxygen-rich hydrazine derivatives (hydrazine modified with —NO₂ and NO₃[−] groups) were envisioned with lots of phantasy and then computationally optimized to obtain molecular geometries and electronic structures [374]. Some basic properties such as bond dissociation enthalpy, density, natural bond orbitals, thermodynamic parameters, molecular orbital energy, and strand-burning rates were then calculated. Predicted performance was excellent, with significant superiority over traditional oxidants found in current propellants. The performance of the as yet unknown 1,2-dinitrohydrazine: O₂NNHNNHNO₂ and nitrohydrazinium nitrate O₂NNHNNH₃NO₃ was compared with that of the well-known hydrazinium(1+) nitrate. The predicted strand-burning rates were compared in Figure 50.

Hydrazinium salts of alkylhydrazines will be described in *Encyclopedia of Liquid Fuels*, chapters “Alkylhydrazines,” “Dimethylhydrazines,” and “Methylhydrazine.” This includes hydroxyethylhydrazinium nitrate, which is used as a fuel in HAN-based monopropellants. The alkylammonium nitrates and perchlorates were dealt with immediately following the free amines in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines,” and they can be compared with alkylhydrazinium salts.

Figure 50: Predicted strand-burning rates of 1,2-dinitrohydrazine and nitrohydrazinium nitrate in comparison with other oxidizers. (Republished and modified from [224], with permission of © 2013 Springer; permission conveyed through Copyright Clearance Center, Inc.)

Hydrogen Peroxide

1 General Information on Hydrogen Peroxide

Hydrogen peroxide, H_2O_2 , also known as hydroperoxide, hydrogen dioxide, CAS RN [7722-84-1], is a colorless liquid with a chemical composition and appearance similar to that of water, but with distinctly different physical and chemical properties. The compound is sometimes erroneously called “hydrogen superoxide”. This is incorrect because hydrogen superoxide refers to unstable hydrogen oxides containing more than two oxygens. A commonly used abbreviation for H_2O_2 in the English-language rocket propulsion literature is HP or HTP, which stands for **high-test peroxide**.

Although this chapter deals with hydrogen peroxide H_2O_2 as a rocket propellant, properties on its isotope analog (isotopologue) D_2O_2 are sometimes listed here for comparison, in particular in Section 3.11 on spectroscopic properties. For one, there is always some D_2O_2 and DHO_2 present in commercial H_2O_2 due to the natural isotope distribution in water and hydrogen the chemical is made from, and this small percentage may affect some of the physical properties. Although D_2O_2 will not be used as a rocket propellant, some of its properties were included here for reference, nevertheless.

This chapter in *Encyclopedia of Oxidizers* gives the physical and chemical properties of hydrogen peroxide as a chemical. *Encyclopedia of Monopropellants*, the chapter “Hydrogen Peroxide” will give a summary on hydrogen peroxide as a monopropellant. A future *Encyclopedia of Hypergolic Bipropellant Combinations*, the chapter “Hydrogen Peroxide” will give a summary on hypergolic bipropellant combinations with hydrogen peroxide as the oxidizer. A future *Encyclopedia of Non-hypergolic Bipropellant Combinations*, the chapter “Hydrogen Peroxide” will give a summary on non-hypergolic bipropellant combinations with hydrogen peroxide as the oxidizer.

1.1 Monographs and Bibliographies

There have not been many new monographs devoted exclusively to hydrogen peroxide in the past 30 years, but many of the older standard most-quoted references are still in use, see [1–6], and additional summary reports and book chapters have become available [7–10]. The best summary on the safety properties of hydrogen peroxide is a NASA report [11]. There are detailed chapters on hydrogen peroxide in many of the popular encyclopedias that serve as standard reference sources for all chemists [12–15]. Other books deal with applications of hydrogen peroxide in the chemical industry but are of less interest to a rocket propellant chemist [16, 17]. There are also several books on hydrogen peroxide in foreign languages [18–20].

1.2 Manufacturers' Literature

Manufacturers' literature continues to be a valuable source of information on hydrogen peroxide, although it may become irrelevant or obsolete quickly. The author has a file of ancient hydrogen peroxide literature that is obsolete and now has only historical value. We hesitate to reference manufacturers' literature that is no longer available or has only historical value, but here is a list of references leading the reader to what once was available and continues to be referenced by other authors: [21–28]. It would be useful to scan these documents and post them on a website for access to all propellant chemists.

One of the best company brochures for hydrogen peroxide properties, uses, storage, and handling was the booklet that was once provided by the Shell Chemical Co., Ind. Chem. Div. [29]. It contained an annotated list of 338 references that are otherwise nearly impossible to obtain.

On the other hand, just because the documents are no longer available to the general public, it is important to summarize the data contained therein and relay them on to future generations of chemists, so the measurements do not have to be repeated. Many of the former manufacturers of concentrated hydrogen peroxide (Becco, Shell) have either gone out of business, discontinued their involvement with HTP, or been acquired by other chemical companies and now operate under different names. Today, there are still many chemical companies that manufacture 70% hydrogen peroxide as a bleaching agent for paper and pulp mills and for wastewater treatment, but only a few of those have the capability of manufacturing more concentrated or stabilizer-free H_2O_2 solutions for rocket applications.

1.3 Literature Surveys

There are many review articles with summaries about the industrial production of hydrogen peroxide [30]. The situation in the industry changes rapidly in the course of one decade, and these reviews need to be updated periodically. There were once dedicated JANNAF meetings on hydrogen peroxide and its application in rocket propellants. Most of the older literature on hydrogen peroxide is difficult to locate and may be obsolete by now [31].

1.4 Internet Resources

URLs of websites change periodically, and the following information may have only limited value. URLs change as often as the weather. It is not always possible to amend a URL with the notation of "Last accessed on ... (date)" and keep it up to date.

As of 2021, a very good website of information on hydrogen peroxide was maintained by USPeroxide for non-rocket applications [32].

Thermodynamic properties of H_2O_2 (and D_2O_2) can be found at the NIST Chemistry WebBook [33] and the NIST Standard Reference Database Number 69 website [34].

As of 2021, a good summary of HTP history was still posted on the surviving archived website [35] of the late General Kinetics LLC, the one-time provider of HTP monopropellant thrusters and gas generators in the US. It included a history of the several phases of HTP development.

1.5 Other (Competing or Non-competing) Applications for Hydrogen Peroxide

Other uses for hydrogen peroxide will consume many orders of magnitude more of this chemical than has ever been used or will ever be used in rockets. The market price for hydrogen peroxide is determined by the other uses and is not affected by the small amount that goes (went) into rocket propulsion. Hydrogen peroxide is an important industrial chemical and is widely used as a disinfectant and bleaching agent and for wastewater treatment and deodorization. Many attractive movie actors owe(d) their blond hair to bleaching with hydrogen peroxide. For industrial applications hydrogen peroxide is usually transported as a 70% solution, although it is rarely used at this concentration. For the large community of H_2O_2 manufacturers and users, it is just more economical not to carry too much water between points of manufacture and end use. A good compromise between transport economics, storage stability and handling safety is 70% H_2O_2 , which is then diluted with water at the point of end use. Food grade H_2O_2 is often shipped as a 35% solution. In the analytical chemical laboratory, 30% H_2O_2 is a common, stabilizer-free analytical reagent that is usually diluted for further use.

In addition to H_2O_2 itself, many peroxy compounds prepared with the use of H_2O_2 have a variety of uses, including as food additives such as calcium peroxide for the artificial aging of flour before baking bread. Other industrial applications for hydrogen peroxide include the production of sodium percarbonate, sodium persulfate, and sodium perborate, used as mild bleaching agents in laundry detergents.

Hydrogen peroxide is used in the production of certain organic peroxides such as dibenzoyl peroxide, which are then used in polymerizations and other chemical processes. Hydrogen peroxide is also used in the production of epoxides from alkenes. The reaction of H_2O_2 with carboxylic acids produces corresponding peroxy acids. Peracetic acid and *m*-chloroperoxybenzoic acid are prepared from acetic acid and *m*-chlorobenzoic acid, respectively, which can be reacted with alkenes to give the corresponding epoxide.

The French PCUK (later Atochem) process for a halogen-free production of hydrazine hydrate [36] is based on hydrogen peroxide, such that some of the new hy-

drazine hydrate production facilities were colocated with existing hydrogen peroxide production sites for logistic reasons [17].

Recently, the development of a process for the production of 1,2-propylene glycol by the oxidation of propylene has evolved as a new application for hydrogen peroxide. Large 1,2-propylene glycol production facilities now under construction have their own hydrogen peroxide production unit nearby for captive use. 1,2-Propylene glycol is used as a deicing fluid on airplanes, as a less toxic anti-freeze for winterizing drinking water systems (for example, in recreational vehicles), as a moisturizer in cosmetics, and many more applications.

There are many well-established and many more potentially new applications for hydrogen peroxide, but they do not all require hydrogen peroxide to be in such high concentrations as the rocket applications do [37].

Looking into the crystal ball and trying to predict future applications for hydrogen peroxide takes a lot of imagination. Nevertheless, a promising future has been predicted for other non-propulsive applications for hydrogen peroxide [38].

1.6 Applications as a Rocket Propellant

The application of hydrogen peroxide as a rocket propellant plays (and has played) only a minor role in the market situation for hydrogen peroxide as a bulk chemical as long as one stays with 70% H_2O_2 , which has many other uses. However, for higher concentrations above 90%, the only major use of this type of hydrogen peroxide is as a rocket propellant. In this application, hydrogen peroxide can serve as a monopropellant as well as an oxidizer in liquid bipropellant and hybrid rocket propellant combinations. Looking at the history of hydrogen peroxide development helps to better understand its potential advantages and disadvantages [39]. Monopropellant applications will be discussed in *Encyclopedia of Monopropellants*. Liquid bipropellant combinations with hydrogen peroxide will be discussed in later sequels for hypergolic and non-hypergolic combinations. Hybrid rockets with hydrogen peroxide may be discussed in future volumes.

Since 1934, hydrogen peroxide has played an important and historical role in the pioneering development of rocket engines as an extension of prior work on torpedo and submarine propulsion systems based on this chemical. The pioneering work was conducted by H. Walter at a shipyard in Kiel, Germany, leading to rocket engines with the model designations 109–500, 109–507 and 109–509. The 109–509 engine was used in the piloted interceptor Me-163B, which was the first piloted airplane to exceed the 1000 km/h speed limit in horizontal cruise. Other applications during WWII were in piloted airplanes such as He-52, FW-56, NATTER and in jet-assisted take-off (JATO) units. The monopropellant applications in steam generators, torpedoes, submarines,

rockets, rocket planes, and satellites are based on the exothermic decomposition of hydrogen peroxide into water (steam) and hydrogen peroxide

The monopropellant engines have been called “cold” engines (as opposed to bipropellant engines in which hydrogen peroxide serves as the oxidizer with a combustible fuel). “Cold” can only be understood as a relative statement since the chamber temperature in “cold” rocket engines and steam generators can well exceed 763 K (490 °C).

After WW-II, initially all testing in the UK used 80% German hydrogen peroxide, which had been impounded at various locations. Eventually, local industries evolved in the UK and in the US, which were capable of producing HTP. As the development progressed, hydrogen peroxide/kerosene engines were widely used in England to power rocket airplanes, jet-assisted take-off (JATO) units, missiles, and satellite launch vehicles [40].

1.6.1 The “pros” and “cons” of Hydrogen Peroxide as a Rocket Propellant

Regardless of whether we discuss the advantages and disadvantages of HTP as a rocket propellant if it is used as a monopropellant or as an oxidizer in bipropellant or hybrid engines, there are some advantages and disadvantages that apply to either application when HTP is compared with other storable rocket propellants. There are many polemic publications on this sometimes hotly debated topic, and we can bring up only a few for discussion here. Quite often, the discussion is reiterated and brought back to the surface by marketing personnel and not necessarily by technically trained engineers or scientists.

One of the author’s favorite writers in rocket propulsion history writings, John D. Clark in his 1972 book *Ignition!*, wrote an unfavorable assessment of HTP and listed the following disadvantages (quoted verbatim here) [41]:

- “peroxide and fuel mixtures can detonate
- peroxide could explode if exposed to gross contamination
- peroxide is not stable and is dangerous in storage
- peroxide has ignition problems and is hypergolic only with hydrazine
- peroxide has an undesirably high freezing point.”

Proponents of HTP use took issue with these unfavorable assessments and tried to disarm each of the arguments [42]. As to detonability, Clark should have cited test results using standard test methods accepted in the propulsion community, such as American Society for Testing and Materials (ASTM), United States Bureau of Mines (USBM), Joint Army Navy Air Force (JANAF) or Interagency Chemical Rocket Propulsion Group (ICRPG) test methods, instead of quoting anecdotal information. As to gross contamination causing explosions, peroxide should not be singled out for special attention. Similar explosions could occur with other rocket propellants (N_2H_4 , LOX) if contam-

inants are negligently allowed to enter the system. The third point, lack of storage stability, is generally recognized, continues to be an unresolved issue, and must be included in mission planning. There are many storage tests reported in the literature (Section 7.1.1.3) and differences in results from different laboratories are typically due to the different passivation methods used for the storage vessels, the different amounts of stabilizers added, or errors occurring in sampling and analysis.

At the time when Clark wrote his landmark book, it may have been true that the only fuel found to be hypergolic with HTP was hydrazine (hydrate), but in the 50 years since he wrote that book, several readily available fuels have been doped with catalysts and additives that make them hypergolic with HTP (to be seen in a future *Encyclopedia of Hypergolic Bipropellant Combinations*).

Finally, the high freezing point of HTP is no less of a disadvantage than the high freezing point of anhydrous hydrazine, which has not prevented spacecraft designers from using hydrazine in thousands of satellites and dozens of space probes. There is usually enough electric power on board the satellites to heat the tanks and lines and prevent the propellants from freezing. In any case, the argument that HTP is frequently supercooling and that supercooling will expand the useful liquid range is naive. Nobody would want to rely on supercooling to prevent the propellant from freezing if the spacecraft ends up in the shadow of the Earth or the tank and line heaters fail in orbit.

Altogether, during the past 50 years, Clark's arguments have lost weight, and some have been proven to be unsubstantiated, but some of the other disadvantages of HTP persist.

1.7 Application of Hydrogen Peroxide in Steam Generators

Steam generators generating high-pressure superheated steam to drive aspirators (jet pumps) for "pressure recovery" in chemical lasers is one of the new applications for hydrogen peroxide, both on the ground and in airborne chemical lasers. This application will be discussed in detail in *Encyclopedia of Monopropellants*.

In 2003, the Defense Logistics Agency [43] issued a request for bids for a 3-year supply contract for 518 metric tons (1161000 lbs) of Hydrogen Peroxide, Type 70, Bulk, IAW, Item Description, H_2O_2 dated 20 December, 2002, FOB White Sands Missile Range, NM. It is assumed that much of this hydrogen peroxide was used for chemical laser tests.

Less concentrated hydrogen peroxide is used as a water treatment and water analysis chemical. The National Stock Number for the 30% Hydrogen Peroxide is 1H 6810 01-044-4188 X2.

The need for HTP with higher and higher concentrations was driven by the desire of rocket propulsion engineers to achieve higher specific impulse with lighter dry system masses. A good summary of HTP history was once provided at the website [44] of General Kinetics LLC, the one-time provider of HTP monopropellant thrusters and gas

generators in the US. Another good historical summary was compiled by a veteran of the hydrogen peroxide usage in the UK [45].

2 Production of Hydrogen Peroxide

2.1 Natural Occurrence of Hydrogen Peroxide

Hydrogen peroxide occurs naturally and is an important intermediate in the metabolism of many living things, including humans. Hydrogen peroxide helps living cells breathe and digest hydrocarbons to derive energy and is part of vital hydroxylation and oxidation reactions. Traces of hydrogen peroxide have even been detected in the air exhaled by humans [46]. In this case, and in very small concentrations, it cannot be that dangerous after all.

A most unusual occurrence of hydrogen peroxide in nature was discovered in studying the defense mechanism for the African bombardier beetle (*Stenoporus insignis*), which in its body produces H_2O_2 solutions up to a concentration of 28% H_2O_2 . The spray of the beetle contains *p*-benzoquinones, compounds well known for their irritant properties, which are ejected at a temperature of $\sim 373\text{ K}$ (100°C). The hot fluid is generated explosively at the moment of ejection by mixing two streams of chemicals stored in separate bladder-shaped glands. The larger of two glands contains premixed 10% hydroquinones and 25% hydrogen peroxide while the smaller one contains a mix of enzymes (catalysts, specifically, catalases and peroxidases). To activate the spray, the beetle mixes the contents of the two compartments, causing oxygen to be liberated from the hydrogen peroxide and the hydroquinones to be oxidized by the free oxygen, which is an exothermic reaction. The free oxygen also acts as the pressurant gas to squirt the hot corrosive solution in a defensive posture on the beetle's enemies, which are usually large ants. The discharges are accompanied by audible popping noises. This is like a monopropellant rocket, and this is why a picture of the bombardier beetle in action is shown in Figure 49.

In the non-living world, H_2O_2 occurs naturally in the high atmosphere as a result of water photolysis by UV and ionizing radiation and the decomposition of ozone in the presence of water vapor.

2.1.1 Natural Occurrence of Hydrogen Peroxide on Earth

Concentrations of H_2O_2 found in the atmosphere vary with the intensity of solar radiation, humidity, and temperature. About twice as much H_2O_2 is formed at 100% relative humidity than at 50% humidity (ambient temperature $298\text{ K} = 25^\circ\text{C}$). During daytime H_2O_2 concentrations range from $0.4\text{--}4\text{ }\mu\text{g}/\text{m}^3$, falling to below $0.01\text{ }\mu\text{g}/\text{m}^3$ at night. H_2O_2 in the atmosphere tends to concentrate into cloud droplets (where concentrations in the liquid can reach $8000\text{ }\mu\text{g}/\text{L}$) and is removed by rain-out. During fog

and severe smog, atmospheric concentrations may rise to $4000\mu\text{g}/\text{m}^3$. Seasonal differences between summer and winter can cause concentrations to vary by a factor of 16. Ice cores taken from glaciers in Greenland or Antarctica show measurable quantities of H_2O_2 down to a depth of 22km, giving us a historical account of hydrogen peroxide prevalence in the atmosphere over several hundred years. Hydrogen peroxide formed in the upper atmosphere may be stabilized and its lifetime extended if it condenses on suspended dust or ice particles.

During the Proterozoic Era, Earth experienced two intervals with one or more episodes of low-latitude glaciation, which are called “Snowball Earth” events [47]. Although the severity of the historical glaciations is debated, theoretical “hard snowball” conditions are associated with the nearly complete shutdown of the hydrological cycle. It has been proposed that, during such long and severe glacial intervals, a weak hydrological cycle coupled with photochemical or radiochemical reactions involving water vapor, liquid, or ice would give rise to the sustained production of hydrogen peroxide, which would then be preserved in the glacial ice, away from sunlight. The photochemical production of hydrogen peroxide was proposed previously as the primary mechanism for oxidizing the surface of Mars. During a Snowball Earth glaciation, hydrogen peroxide could be stored in the ice [48]. Hydrogen peroxide is a good storage medium for oxygen. Upon melting during the next warming period, H_2O_2 would then be released directly into the ocean and the atmosphere, decompose to release molecular oxygen, and could mediate global oxidation events in the aftermath of the Snowball glaciation. Similar conditions may still exist on other planetary bodies or their icy moons.

Hydrogen peroxide plays a key role in atmospheric pollution, where it may combine with nitric acid and acetic acid in the atmosphere or react with suspended aerosols. Peroxynitric acid and peroxyacetic acid are the most irritating contaminants in urban smog.

Heterogeneous reactions of H_2O_2 on aerosols suspended in the air may play an important role in tropospheric chemistry. The heterogeneous reactions of H_2O_2 vapor on SiO_2 and $\alpha\text{-Al}_2\text{O}_3$ particles, two major components of mineral dust aerosol, was studied using transmission-Fourier Transform InfraRed (T-FTIR) spectroscopy and high-performance liquid chromatography (HPLC) [49]. In looking for H_2O_2 sinks in the atmosphere, it was found that H_2O_2 molecularly adsorbs on SiO_2 , and a small amount of molecularly adsorbed H_2O_2 decomposes due to its thermal instability. For $\alpha\text{-Al}_2\text{O}_3$, some decomposition of H_2O_2 evidently occurs, but there is also a small amount of H_2O_2 molecularly adsorbed on the particle surface. Heterogeneous reactions of H_2O_2 on suspended mineral oxide dusts play a significant role in atmospheric chemistry. Similar reactions, but at much higher H_2O_2 concentrations, occur with H_2O_2 on the surface of catalysts in rocket engines.

Surface water H_2O_2 concentration in the North Pacific Ocean varied from less than 10 to more than $250\text{nmol}/\text{L}$ [50]. The net rate of photoproduction in the ocean near Hawaii in full sunlight was determined to be $8\text{nmol}\text{L}^{-1}\text{h}^{-1}$, similar to rates reported

for the central Atlantic Ocean and Antarctic. However, this maximum estimate of photoproduction is also similar to probable rates of H_2O_2 input from other mechanisms (biological production and rain). This concentration of H_2O_2 is too low to economically win hydrogen peroxide from seawater, but its presence affects the oxygen cycle of biota in the ocean.

The concentration of hydrogen peroxide in rainwater over the South and Central Atlantic Ocean varied from 3.5 to $71\text{ }\mu\text{M}$ with an average ($n=25$) and a standard deviation of 26 and $22\text{ }\mu\text{M}$, respectively [51]. These values are similar to previously reported average hydrogen peroxide concentrations in marine rainwater of the Gulf of Mexico ($40\text{ }\mu\text{M}$), the western Atlantic Ocean ($13\text{ }\mu\text{M}$), and Florida Keys ($28\text{ }\mu\text{M}$).

2.1.2 Natural Occurrence of Hydrogen Peroxide on Mars

The presence of extraterrestrial hydrogen peroxide has also been reported on the surface and in the atmosphere of Mars and the Jupiter moon Europa [52]. If the concentrations there are high enough to harvest the materials as a rocket propellant, this would open new methods of in-situ resource utilization (ISRU) for future manned spaceflight to those destinations. The presence of perchlorate in ice on Mars also indicates that the surface chemistry is highly oxidizing, making it more difficult for life forms (as we know them) to thrive.

Direct observations of hydrogen peroxide in the atmosphere of Mars were rare until recently. Ever since the Viking mass spectrometer failed to detect organics on the surface of Mars in 1976, H_2O_2 has been suggested as a possible oxidizer of the Martian surface. However, the search for H_2O_2 on Mars was unsuccessful for three decades. In 2003, H_2O_2 was finally detected using two terrestrial ground-based independent techniques, first with submillimeter heterodyne spectroscopy and then again with thermal infrared imaging spectroscopy. A few available observations and most 1-D model simulations suggested an H_2O_2 column in the range from 10^{15} to 10^{16} molecules/ cm^2 or a mixing ratio in the lower atmosphere of nearly 10–30 ppb.

The 362.156 GHz absorption spectrum of H_2O_2 in the Mars atmosphere was observed in 2003 through the James Clerk Maxwell Telescope submillimeter facility on Mauna Kea, Hawaii [53]. Radiative transfer analysis of this line absorption yielded an average volume mixing ratio of 18 ± 0.4 ppbv within the lower (0–30 km) Mars atmosphere, in general accordance with standard photochemical models

Another estimate of the content of hydrogen peroxide in the atmosphere of Mars used an atmospheric general circulation model with chemistry kinetics [54]. These simulations confirmed the correlation between the amounts of water and hydrogen peroxide and predicted an important role for condensation of H_2O_2 in the polar regions.

Concentrations of H_2O_2 in the Mars atmosphere have been mapped over the seasons using an imaging spectrometer at a large terrestrial astronomical observatory with an infrared telescope. New maps of Martian water vapor and hydrogen perox-

ide distribution were obtained in 2005 using the Texas Echelon Cross Echelle Spectrograph at the NASA Infra-Red Telescope facility at Mauna Kea Observatory [55]. The inferred mean H_2O_2 abundance was 15 ± 10 ppb, which is significantly lower than the 2003 result and lower than expected from photochemical models, taking into account the change in season. Its spatial distribution showed some similarities with the map predicted by models

Submillimeter heterodyne spectroscopy has been used to simultaneously monitor the abundances and spatial distributions of H_2O_2 and H_2O on Mars as a function of the seasonal cycle [56]. A comparison with global climate models showed that the observations favor simulations taking into account heterogeneous chemistry. It has been suggested that large amounts of hydrogen peroxide could be generated by triboelectricity during dust storms or dust devils.

Because many life forms are not resistant to hydrogen peroxide, its presence on extraterrestrial bodies very much limits life forms as we know them. On the other hand, extremophiles have learned to adapt to environmental conditions (acidity, temperature, lack of oxygen) under which other life forms would be quickly eradicated. Extremophiles living in a cold climate (as on Mars) will need an anti-freeze in their water-based blood to thrive. Hydrogen peroxide lowers the freezing point of water. It has been speculated that extremophiles might even adapt to an oxidizing environment and use low-freezing $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ liquids as their biological fluid and source of oxygen [57, 58]. That might even explain some of the Viking Lander 1976 biology experiment results. Possible overall metabolic pathways are:

The source of energy for these reactions to take place might be electric discharges in the dust devils that have been seen swirling across the Mars scape. The presence of H_2O_2 in the polar caps of Mars (along with the prevalence of ozone in the atmosphere) might even have implications for future extraterrestrial in-situ resource utilization by concentrating the H_2O_2 from the polar ice and using it as a rocket propellant or as a source of breathing oxygen for the astronauts. H_2O_2 may also be chemisorbed or included in the sphere of hydration of minerals on the surface of Mars, one explanation for the oxygen evolution observed during the Viking experiments when water was added to Martian soil. However, the Mars Phoenix Lander did not identify H_2O_2 (but it found ClO_4^-) [58].

2.1.3 Natural Occurrence of Hydrogen Peroxide in Icy Moons

Many of the moons revolving around the big planets Jupiter and Saturn are worlds of ice, some even with geysers spouting ice crystals. It has been speculated that it would

be difficult for life as we know it to exist on Europa because the ice is rich in hydrogen peroxide from being bombarded by cosmic radiation and immersed in a cloud of ions from Jupiter's radiation belt.

Ice samples at 16 and 77 K were irradiated with 30 keV singly charged H, C, N, O, and Ar ions. By measuring the absorption of the hydrogen peroxide band by *in-situ* infrared spectroscopy between 3.50 and 3.52 μm (2860 and 2844 cm^{-1}), it was found that H_2O_2 is produced at the two different temperatures by all the different ions tested [59]. This result showed that H_2O_2 may be produced by radiolysis of water ice on the surface of the satellite Europa. The amount of H_2O_2 produced by N and Ar implantation did not vary significantly with temperature but notably for H and especially for O more H_2O_2 was produced at 77 K than at 16 K.

Spatially resolved IR and UV wavelength spectra of Europa's leading, anti-Jovian quadrant observed from the Galileo spacecraft showed absorption features resulting from hydrogen peroxide [60]. Comparisons with laboratory measurements indicated surface hydrogen peroxide concentrations of about 0.13%, by number of mols, relative to water ice, the matrix for frozen H_2O_2 . The inferred abundance was consistent with radiolytic production of hydrogen peroxide by intense energetic particle bombardment and demonstrated that Europa's surface chemistry is dominated by radiolysis.

Radiolysis and photolysis are the chemistry that follows the bond breaking and ionization produced by incident radiation, producing H_2O_2 , $\cdot\text{OH}$, O_2 , and a little H_2 from irradiated H_2O ice [61]. Sputtering is the ejection of molecules by incident radiation. Both processes are particularly effective on ices in the outer solar system, which may be transported from one planetary body to another.

Would it not be nice to land on one of these bodies and find a polar cap of frozen H_2O_2 , ready to be scooped up and used as propellant for the return trip? Further ISRU studies will try to answer that question.

2.1.4 Natural Occurrence of Hydrogen Peroxide in Interstellar Space

Hydrogen peroxide formed in interstellar space may be stabilized if it condenses on interstellar dust or ice particles [62].

Hydrometeorites, rarely found clumps of cometary and primordial ice that survive the plunge through the Earth's atmosphere, probably contain hydrogen peroxide from the long exposure to cosmic radiation, but once they arrive on Earth they are rarely preserved long enough to be analyzed and most often melt before someone has a chance to put them into a freezer compartment and preserve them for later analysis.

2.2 Other Sources of Hydrogen Peroxide

A potential source of H_2O_2 for human consumption is from drinking water that has been sterilized with ozone and UV radiation. The authorized residual concentration of H_2O_2 in potable water is 0.1 mg/L in the USSR and Germany and 0.5 mg/L in France.

In addition to its applications in rockets and the chemical industry, hydrogen peroxide is a major reactive oxygen species in living organisms. Its overproduction in cellular mitochondria is implicated in the development of many severe diseases such as cancers and neurodegenerative Parkinson's and Alzheimer's diseases. It would, therefore, be very useful if one could visualize the H_2O_2 spatial distribution and concentrations in living cells by a yet to be developed imaging technique.

Traces of H_2O_2 form due to recombination of hydroxyl-free radicals in an oxygen/hydrogen torch if the hot flame is impinging on a block of ice, quenching the reaction products (Section 2.5.1.)

2.3 The Postulated Existence of Other Oxides of Hydrogen: Hydrogen Polyoxides

It would be nice to stabilize some hydrogen polyoxides and use them as rocket propellants. These would be energetic, clean oxidizers with a higher oxygen content and even more powerful than hydrogen peroxide. Stabilization may be possible by trapping them in a matrix of solid oxygen or suspending them as a slush in liquid oxygen. In connection with the simplest peroxide, $\text{H}-\text{O}-\text{O}-\text{H}$, we also want to mention efforts to synthesize peroxy compounds with two or three $\text{O}-\text{O}$ bonds in the molecule, such as hydrogen tetraoxide, H_2O_4 , CAS RN [29683-94-1], also called hydrogen tetroxide or hydrogen superoxide, with a postulated structure of

In addition to linear superoxide molecules, branched or ring structures with four or more $\text{O}-\text{O}$ bonds have been theorized. It was attempted to synthesize superoxide compounds by reaction of atomic hydrogen with H_2O_2 vapor or liquid ozone and quenching the reaction products by flash-freezing them. A group of Russian authors started reporting work on H_2O_4 in 1956 and claimed to have isolated H_2O_4 in products of a glow discharge in water and by reaction of atomic hydrogen with ozone [63–68]. The glow discharge in water is said to have produced 15% H_2O_4 , and the ozone/hydrogen reaction is said to have produced a 60% H_2O_4 concentration, but that could not be confirmed. However, the material was stable only at very low temperatures (83 K = -190°C), and for a long time it was not certain if this is a compound or a trapped collection of $\text{HOO}^\bullet$ free radicals in a matrix of other products [69].

The magnetic properties of peroxide-radical condensates synthesized from dissociated water vapor and also obtained from the reaction of atomic hydrogen and liquid 100% ozone in the temperature range 123 to 293 K (-150 to 20°C) showed that before

the start of decomposition (below 163 K = -110 °C), the peroxide-radical condensates were weakly diamagnetic with a susceptibility of -0.1×10^{-6} to -0.2×10^{-6} CGSM [70]. With increased temperature there was increased paramagnetism, associated with the appearance of oxygen released on the decomposition of the peroxide radical condensate. The data indicated that the molecular oxygen released on decomposition of the peroxide-radical condensates does not appear in the condensates in the adsorbed or occluded form, but forms as a result of the decomposition of the unstable compound H_2O_4 , a higher peroxide of hydrogen which has linear structure: $\text{H}-\text{O}-\text{O}-\text{O}-\text{O}-\text{H}$.

It was attempted to prepare higher oxides of hydrogen by electrolysis and UV irradiation of dilute hydrogen peroxide solutions, but this did not produce any higher peroxides [71]. The reactions of hydrogen atoms with ozone at 77 K = -196 °C gave compounds behaving like superoxides, presumably $\text{HOO}^\bullet$ and H_2O_4 . These species decomposed at 153 and 183 K (-120 and -90 °C), respectively, to give molecular O and H_2O_2 . The heat of formation is $+54 \pm 41$ kJ/mol ($+13 \pm 10$ kcal/mol) for HO_2 and -8.3 ± 41 kJ/mol (-2 ± 10 kcal/mol for H_2O_4). The products obtained from H_2O and H_2O_2 in a discharge tube and by the reaction of H atoms with O were compared to the peroxides formed in the hydrogen atom/ozone reaction.

The infrared absorption of products from electrically dissociated H_2O or D_2O vapor and other hydrogen-oxygen systems trapped at liquid nitrogen temperature was measured between 4000 and 300 cm^{-1} in search of higher polyoxides like H_2O_3 or H_2O_4 [72]. Four new absorption bands were found in the deuterated systems at 857, 820, 760, and about 440 cm^{-1} . By isotopic substitution of ^{18}O the frequencies were shifted to 806, 775, 717, and $\sim 420\text{ cm}^{-1}$ as was expected for O—O vibrations. In the hydrogen systems, this region was obscured by the strong libration bands of H_2O and H_2O_2 molecules. Temperature and composition effects showed that more than one new species was involved. Accordingly, the new spectra were assigned to the often postulated polyoxides, H_2O_3 or H_2O_4 , stabilized in the water-peroxide matrix. The more abundant, and also more stable, H_2O_3 has a half-life of some 5 h at 208 K (-65 °C). The observed frequencies were consistent with zigzag chain structures linked by single covalent bonds as already observed in the more stable hydrogen polysulfides. Relative concentrations of the polyoxides were estimated at 5 to 10 mol-%, depending on the composition of the starting material. It remains to be seen whether these compounds can be stabilized and used as rocket propellants.

The kinetics of oxygen evolution on warming the trapped products (at 77 K = -196 °C) from water H_2O or H_2O_2 vapor dissociated in a glow discharge were studied by a manometric method [73]. Under closely controlled conditions it was possible to clearly distinguish the onset of decomposition of the two intermediates, H_2O_3 and H_2O_4 . The latter begins to decompose measurably following crystallization of the glassy solid at about 158 K (-115 °C), and the H_2O_3 decomposes readily between 223 and 238 K (-50 and -35 °C). It has been suspected that the gas evolution at that stage is mainly a physical desorption process and not the decomposition of a chemical compound. Typically, the yields of H_2O_3 from dissociated H_2O vapor were of the

order of 3–5 mol-%, but those of H_2O_4 were only about one-tenth as much. It was attempted to optimize the yield by varying the distance between the microwave discharge and the cold trap. Only a small fraction of the peroxide is formed via the H_2O_4 intermediate in these systems. More of the higher oxides were obtained from dissociated H_2O_2 than from H_2O vapor. The deuterated systems showed some unusual isotope effects. The yields of D_2O_3 were always higher (up to twice and even more) than those of H_2O_3 under similar conditions. The deuterium polyoxides decomposed at slightly higher temperatures (10–15°) than their hydrogen analogs.

Peroxy-radical condensate (PRC) is a yellowish glassy substance that is formed during the condensation of H_2O and H_2O_2 vapors dissociated in an electrical discharge, mixtures of $\text{H}_2 + \text{O}_2$, as well as the products of the reactions $\text{H} + \text{O}_3$ (liq), $\text{H} + \text{O}_3$ (gas) or $\text{H} + \text{O}_2$ (gas) on a cold (77 K) surface [74]. The yield of $\text{HO}_2^\bullet$ and H_2O_4 in a glow discharge of hydrogen-oxygen mixtures depends on many operating variables, including pressure [75], temperature [76], or the type of reactor vessel wall materials [77]. The peroxy-radical condensate has been analyzed by many methods, including IR spectroscopy [78], Raman spectroscopy [79], X-ray diffraction (XRD) [80], electron-proton resonance spectroscopy (EPR) [81], and other methods [82, 83].

X-ray studies of the products of the reaction of atomic hydrogen and liquid ozone have shown that the hydrogen atom-ozone product as formed does not contain hydrogen peroxide [80]. Upon warming to 195 K (–78 °C) some hydrogen peroxide is produced. The higher polyoxide product is not a well-defined crystalline compound and its presence could only be hinted by a halo at about 3.4 Å.

The kinetics of low-temperature reactions leading to the accumulation of $\text{HO}_2^\bullet$ [84] and formation of H_2O_4 by recombination of $\text{HO}_2^\bullet$ radicals [85] or premature dissociation of H_2O_4 need to be better understood before one can optimize the synthesis methods and before one can decide if this work is strictly to satisfy academic interest or if it ever will find a practical application [86, 87]. Instead of analyzing the PRC in search of H_2O_3 and H_2O_4 immediately after it has condensed, it has been common practice to allow the condensate to sit at an intermediate temperature where the $\text{HO}_2^\bullet$ radicals have enough mobility to recombine. The rate of recombination of $\text{HO}_2^\bullet$ radicals during the annealing period depends on their mobility and ability to diffuse through the matrix to find each other [88].

It was shown that at 138 K (–135 °C) the $\text{HO}_2^\bullet$ radicals disappear rapidly. Samples were annealed at 138 K (–135 °C) for over 0.5 h prior to recooling to 77 K (–196 °C). Peroxy-radical condensate (PRC) samples prepared by two different methods were then allowed to decompose in a calorimeter [89]. The heat of decomposition at 77 K (–196 °C) of the PRC superoxide made from dissociated water in a glow discharge was $-74.5 \pm 9.2 \text{ kJ/mol} = -17.8 \pm 2.2 \text{ kcal/mol}$ and the heat of decomposition of the PRC superoxide made from $\text{O}_3 - \text{H}^\bullet$ atom reactions was $-112.1 \pm 10.9 \text{ kJ/mol} = -26.8 \pm 2.6 \text{ kcal/mol}$. Using the value of $-74.5 \pm 9.2 \text{ kJ/mol} = -17.8 \pm 2.2 \text{ kcal/mol}$ for the reaction

at 77 K (−196 °C), the heat of formation of H_2O_4 (S) is $-116.7 \text{ kJ/mol} = -27.9 \text{ kcal/mol}$. The recombination of $\text{HO}_2^\bullet$ radicals will lead to the formation of H_2O_4 . Using literature data for the heat of formation of gaseous $\text{HO}_2^\bullet$ radicals ($+20.9 \text{ kJ/mol} = +5 \text{ kcal/mol}$) and assuming this radical has the same thermal properties as hydrogen peroxide, the heat of reaction at 77 K (−196 °C) of the equation

is $-16.7 \text{ kJ/mol} = -4 \text{ kcal/mol H}_2\text{O}_4$.

The most remarkable property of PRC is its decomposition during heating above 150 K with the release of dioxygen and the formation of a concentrated hydrogen peroxide solution. It is assumed that this is caused by the presence of considerable amounts of higher peroxides H_2O_3 and H_2O_4 in PRC. One of the methods for the synthesis of peroxy-radical condensates is the condensation at liquid nitrogen temperature of an $\text{H}_2 + \text{O}_2$ mixture dissociated in an electrical discharge at low pressure. Peroxy-radical condensates were shown to contain substantial quantities of higher hydrogen peroxides H_2O_3 and H_2O_4 . A study of the influence of experimental parameters on the synthesis of peroxy-radical condensates from an $\text{H}_2 + \text{O}_2$ mixture resulted in recommendations for the optimal experimental conditions for the synthesis in a U-tube electrical discharge reactor with an inner diameter of ~15 mm, immersed in liquid nitrogen, at rather low pressure ($66\text{--}132 \text{ Pa} = 0.5\text{--}1 \text{ Torr}$) [90]. The maximum conversion of initial O_2 into higher hydrogen peroxides was observed at a composition of initial gas mixture of 66.7% $\text{H}_2 + 33.3\% \text{ O}_2$.

It would be difficult to stabilize $\text{HO}_2^\bullet$, H_2O_3 , or H_2O_4 [91]. The best method to preserve these compounds for further investigation is to keep them very cold [92].

Theory predicts that hydrogen trioxide H_2O_3 can occur in two rotational isomers: *cis*-HOOOH and *trans*-HOOOH. A theoretical study of the electronic spectra and molecular structure was able to predict equilibrium geometries of *cis*-HOOOH and *trans*-HOOOH using a density functional theory (DFT) method, a complete active space self-consistent-field method and a coupled cluster with single and double replacement method [93]. The harmonic vibrational frequencies on the optimized geometries were calculated using the DFT method. The potential energy curve of the isomerization between the *trans*-HOOOH and *cis*-HOOOH was obtained by DFT calculations. Computed results showed that the *trans*-isomer should be more stable than the *cis* isomer. There are two possible pathways for the conversion between the *trans*-HOOOH and *cis*-HOOOH.

The structures of polyoxides HOOH, HOOOH, HOOOOH, and HOOO were investigated by computational chemistry employing the CCSD(T) methodology and the correlation consistent basis sets [94]. H_2O_3 and H_2O_4 would make good rocket propellants, if one could stabilize them. For all molecules, fundamental vibrational frequencies, structural parameters, rotational constants, and rotation-vibration corrections were calculated. For HOOOH, a good agreement between calculated results and microwave and IR spectra measurements was achieved, although for the symmetric O—O

stretch some important differences were found. Heats of formation were computed using atomization energies: $\Delta H^\circ_{f,298}(\text{HOOOH}) = -89.9 \text{ kJ/mol}$ (-21.50 kcal/mol) and $\Delta H^\circ_{f,298}(\text{HOOOOH}) = -44.39 \text{ kJ/mol}$ (-10.61 kcal/mol). The $\Delta H^\circ_{f,298}(\text{HOOO})$ was $+23.0 \text{ kJ/mol}$ (5.5 kcal/mol).

Hydrogen tetroxide H_2O_4 and hydrogen trioxide H_2O_3 have been prepared and characterized as components of peroxy radical condensates. The polyoxides were characterized by the Raman spectra of the oxygen framework [79]. Lines at 500, 756, and 878 cm^{-1} correspond to skeletal oscillations of H_2O_3 in the condensate (OOO bend, asymmetric OO stretch, symmetric OO stretch). Lines at 449, 589, 624, 827, and 865 cm^{-1} match the skeletal vibrations of H_2O_4 (OOO bend 1, OOO bend 2, center OO stretch, asymmetric OO stretch, symmetric OO stretch). The line of the O_4 torsion vibration of hydrogen tetroxide was not observed experimentally. For the first time, convincing evidence was now provided for the existence of hydrogen tetroxide (in low-temperature solids).

Hydrogen trioxide, HOOOH , H_2O_3 , CAS RN [14699-99-1], has been prepared by reduction of ozone, decomposition of hydrotrioxides (ROOOH), and by reaction of hydrogen peroxide with ozone and has been identified by infrared (IR), ^1H , and ^{17}O nuclear magnetic resonance (NMR) spectra, and a substantial amount of information on this molecule has been gathered in the meantime [95]. It may even occur naturally; it is just very hard to find at the very low concentrations.

The composition of low-temperature condensates obtained by the reaction of hydrogen atoms with liquid ozone has been determined from the Raman spectra and data of the molar ratio of O_2 to H_2O_2 in the decomposition products [96]. The main constituents are hydrogen tetraoxide H_2O_4 , hydrogen trioxide H_2O_3 , and hydrogen peroxide H_2O_2 in comparable amounts and also some water H_2O . H_2O_4 , H_2O_3 , and H_2O_2 are formed in the diffusion-controlled reactions between OH and HO_2 in the liquid ozone layer and stabilized by transfer to the solid phase. $\cdot\text{OH}$ and $\cdot\text{O}_2\text{H}$ radicals are generated via a sequence of the reactions initiated by the interaction $\text{H} + \text{O}_3(\text{L})$.

2.4 Industrial Production of Hydrogen Peroxide

Before starting to use hydrogen peroxide as a rocket propellant, it helps to know by which process the chemical was produced. Contaminants that are carried over from the reactants during H_2O_2 production may cause problems during its use as a rocket propellant. The types of contaminants differ depending on the process used for the production of H_2O_2 . Military specifications for propellant-grade hydrogen peroxide had to be modified each time a different H_2O_2 production process was brought online. The adverse effects of contaminants depend on the application of hydrogen peroxide, if it is to be used as an oxidizer in a bipropellant engine or as a monopropellant. If hydrogen peroxide is to be used as a monopropellant, the specifications would be more restrictive than if it was to be used as an oxidizer in a bipropellant or hybrid rocket

propulsion system. Stabilizers act as contaminants and may poison catalysts. There are many possible methods for production of hydrogen peroxide:

- production from peroxy compounds
- production from hydrogen and oxygen
- production from carbon monoxide, oxygen, and water
- electrochemical processes
 - Degussa-Weissenstein Process
 - Münchner process
 - production by cathodic reduction of oxygen
- production by autoxidation of organic compounds
 - 2-propanol autoxidation (Shell Process)
 - anthraquinone derivative autoxidation

Of the three main methods that were historically used (in the chronological sequence listed below) for the industrial production of hydrogen peroxide:

- acidification of earth alkaline metal or alkali metal peroxides
- electrolysis of sulfuric acid or ammonium sulfate at high current densities
- oxidation and reduction of anthraquinone derivatives

only the latter method is still in use. The other two methods have been historically important but have long since been replaced due to different economics and concern about disposal of byproducts. Another method for production of H_2O_2 is the cumyl-hydroperoxide method (Hock-process). This process produces acetone and phenol as the main products.

The electrochemical production avoids the use of organics and has the capability of producing a high purity product free of organics contaminants. It is (was) attractive for locations where electric power is (was) cheap. The electrochemical method can also be used for *in-situ* production of H_2O_2 in dilute aqueous solutions for sterilization or wastewater treatment, also in remote locations. All three methods result in dilute aqueous solutions of H_2O_2 , which must subsequently be dehydrated to more economical concentrations for storage and transport. For safety reasons, the concentration process rarely goes beyond 90% H_2O_2 . All concentration steps require pure starting materials and extremely clean process equipment to prevent accidents during processing and lack of storage stability in the shipped product. For use as a laboratory chemical and chemical reagent, a 30% H_2O_2 solution is the most practical concentration and is readily available from most chemical supply companies. Food-grade H_2O_2 is often sold as a 35% solution.

2.4.1 History of the Industrial Production of Hydrogen Peroxide

The interest in hydrogen peroxide as a rocket propellant has fluctuated through periods of high and low interest. In the 1990s, in the wake of increasing concern about

the handling hazards of hypergolic storable bipropellants and monopropellant hydrazine, as part of the search for “green” (i.e., environmentally friendly) rocket propellants, hydrogen peroxide experienced a “renaissance” and several chemical companies embarked on establishing or expanding existing production facilities for HTP.

It helps to get a better understanding of the current situation with hydrogen peroxide if one spends a little time studying the history of hydrogen peroxide production. If the demand for HTP in the US does not increase as predicted by some green propellant supporters, some of the HTP production sites may shut down again.

As of 1961–1966, there were three producers of HTP in the US, and each was using a different process. FMC Corporation was producing HTP by electrolysis of persulfuric acid; E.I. DuPont de Nemours & Company was producing HTP by a modified anthraquinone process, and Shell Chemical Company was producing HTP by high pressure oxidation of isopropyl alcohol. The DuPont and Shell products were usually referred to as “organic” process peroxides. Producers using the electrolytic process claimed that peroxide manufactured by organic processes is inferior in its performance. The significant analytical difference between the various peroxides pertains to the carbon content. All three processes satisfied the military specification (MIL-P-1600SE) requirement of a maximum of 200 ppm carbon. FMC peroxide has a carbon content of approximately 6 ppm, DuPont peroxide approximately 15 ppm, and Shell peroxide approximately 175 ppm. It should be noted, in regard to this variation of carbon content, that no catalyst degradation has been reported to date that could be blamed on carbon contamination.

2.4.2 Electrochemical Processes

The formation of hydrogen peroxide via the electrolysis of aqueous sulfuric acid was discovered in the middle of the nineteenth century. During this electrolysis, peroxodisulfuric acid that forms first is subsequently hydrolyzed by water to give sulfuric acid and hydrogen peroxide via the peroxomonosulfuric acid (Caro’s acid) intermediate. After the change to ammonium sulfate as the starting material, the production of H_2O_2 increased steadily. Until the mid-1950s, around 80% of the H_2O_2 produced globally was made by this route. All electrochemical processes lost their competitiveness after the introduction of the AO process because of their high energy (electric and thermal) costs. Only in places with low energy costs, such as some states from the former Soviet Bloc, did the electrochemical route continue to be used for a few more years.

2.4.2.1 History of Degussa Hydrogen Peroxide Production

As of 1998, Degussa had 87% H_2O_2 available from its production and concentration plant in Rheinfelden, Germany. The capacity of this plant was sufficient to satisfy European demand and even to export some of the product to the US. Degussa was also evaluating the need to produce a more concentrated 90% HTP [97–100]. This production capability, which began as a small semi-batch process carried out in glass-

lined reactors, eventually reached a fully functional level with the startup in 1987 of a vacuum distillation unit exclusively dedicated to the production of HTP.

In 2006, RAG Foundation acquired Degussa AG, which was later renamed Evonik-Degussa GmbH. As of 2008, Degussa Propulse™ was distributed in the US by a new company called *Evonik Industries*. Evonik Industries is an industrial corporation in Germany owned by the RAG Foundation and one of the world's leading specialty chemicals companies. It was created in 2007 as a result of restructuring of the mining and technology group RAG. Evonik Industries united the business areas of chemicals and energy of RAG. As of 2021, Evonik offered three high-concentration hydrogen peroxide products: Propulse™ 825 HTP, Propulse™ 875 HTP, and Propulse™ 980 HTP high-test hydrogen peroxide [101].

In October 2011, a Russian Soyuz-ST carrier rocket launched its first satellite from the Kourou Space Center in French Guiana. The primary propulsion propellant pump was powered by a steam generator for the first time fed with Propulse™ made in Germany.

2.4.3 Organic Chemical Processes

The autoxidation of hydroquinones was the first continuous industrial process for producing hydrogen peroxide but was ultimately replaced in the late 1930s by the Riedel-Pfleiderer or BASF process, which uses alkylated anthraquinones [97]. In 1953, Du Pont of Memphis, Tennessee, commissioned the first hydrogen peroxide production plant in the US based on the AO process. In 1962, Degussa started the first industrial-scale plant using the AO process [102]. In current practice, the auto-oxidation process uses an alkylated anthraquinone (such as 2-alkyl-9,10-anthraquinone or 2-ethyl-9,10-anthraquinone), which first is reduced with hydrogen in the presence of a catalyst to form the corresponding hydroanthraquinone. This hydroquinone is then air-oxidized to yield hydrogen peroxide and 2-alkyl anthraquinone, which is returned to the loop (leaving a trace of organics behind in the H₂O₂ product, which must be removed if it interferes with the intended application). The autoxidation process is carried out in an inert, organic medium. The working solution is typically a proprietary solvent blend chosen for its ability to solubilize both quinones (which dissolve well in non-polar aromatics) and hydroquinones (which dissolve well in polar solvents). Inert, non-volatile solvents used are diisobutylcarbinol and methyl naphthalene, and traces of these may be found in the products. The working solution must be non-toxic and chemically stable in both strongly hydrogenating and oxidative reaction environments. Crude hydrogen peroxide is then extracted with water, and the anthraquinone is recycled back to the hydrogenator for reuse. The aqueous hydrogen peroxide from the extractor has a concentration of only 15–30% H₂O₂ and is contaminated with dissolved organic matter that is formed by the chemical degradation of the working compound (anthraquinone) and the working solution. These organic impurities must be removed by a variety of purification methods, and the peroxide is then sent to a concentration

unit where it is distilled up to active levels of 50–70% H_2O_2 . At this point in the process, the peroxide is treated with chemical stabilizers (typically sodium pyrophosphate and sodium stannate at levels between 0.01 and 0.25%, depending on the grade and intended application) and then transferred into bulk storage tanks. To bring the product up to concentration levels above 70% involves where it begins to be of interest as a rocket propellant, a second distillation process in which additional water is removed. Since pure hydrogen peroxide has a boiling point of 423 K (150 °C), and the favorable fact that water and H_2O_2 do not form an azeotrope (unlike water and hydrazine), vacuum distillation is a viable process that can be used to produce HTP from a 70% starting material. However, there are three important factors that make this distillation process one that requires a high level of technical sophistication in order to be carried out in a safe and efficient manner:

- The non-volatile impurities (e.g., heavy metals) in the product are concentrated as well.
- The H_2O_2 decomposition rate increases about 2.3 times for each 10 °C rise in temperature.
- H_2O_2 vapors above certain concentration limits will decompose explosively, even at ambient temperatures.

2.4.3.1 History of BASF Hydrogen Peroxide Production in Germany

Between 1935 and 1945 BASF developed the anthraquinone process in a pilot plant with a monthly production of 30 metric tons. Two large plants were then constructed at Heidebreck and Waldenberg, each having an annual capacity of 2000 metric tons to support the war effort. Both plants were partially complete when construction was halted at the end of World War II. In 1953, E. I. DuPont de Nemours commissioned the first hydrogen peroxide plant using the AO process in the US, and subsequently the production capacity of hydrogen peroxide was greatly increased every year. In 1996, world capacity stood at 1.3×10^6 metric tons (reported as 100% hydrogen peroxide).

2.4.3.2 History of Solvay Hydrogen Peroxide Production

As of 1998, the Solvay Interlox group of companies was the world's largest producer of hydrogen peroxide with a 24% capacity share of the world market and 18 manufacturing sites that focused exclusively on hydrogen peroxide and its derivatives [103]. As of 2012, Solvay Interlox, Inc. was 100% owned by Solvay America, Inc. which was, in turn, 100% owned by Solvay S.A., a chemical and pharmaceutical company with operations in 41 countries, employing more than 35000 people and headquartered in Brussels, Belgium. The origins of the current group of companies, however, date back to the initially independent operations of Solvay (Belgium) and of Laporte, a UK-based chemical company. The latter company actually began production of hydrogen peroxide more than 100 years ago. In 1970, Laporte and Solvay formed a worldwide joint venture in peroxygen chemicals by the creation of

the Interlox group of companies. In 1992, Solvay acquired a 100% interest in the H_2O_2 activities of Interlox, leaving Laporte to focus on some of the more highly specialized peroxygen compounds, such as organic peroxides.

As of 1998, HTP was still produced in Germany. Solvay Interlox had one of its two HTP producing facilities located near Munich, and this site has produced up to 86% H_2O_2 for many years, primarily for captive use in the manufacture of organic chemicals. The other facility is located in Warrington, England and is a former Laporte site.

Laporte first began production of hydrogen peroxide in the late 1800s using a barium peroxide process to generate solutions of 3% H_2O_2 . This was later replaced with an electrolytic process that provided 35% H_2O_2 , some of which was concentrated via distillation to produce 85% HTP. As new production capacity was added to the growing business, a switch to the autoxidation or AO process was made. Today, all major producers of H_2O_2 utilize AO process chemistry in their plants. Organics employed industrially include 2-*tert*-amylanthraquinone, 2-*iso-sec*-amylanthraquinone, and 2-ethylanthraquinone. Laporte built its first AO process plant at Warrington in 1958, and it was this plant that supplied all of the 85% HTP for the British rocket development programs, including the Black Knight rocket. Initially, the process used a mixture of benzene and secondary alcohols as process solvent. Later, they used cyclohexyl acetate or a mixture of dimethyl phthalate and xylene or trimethylbenzene as the process solvent. As of 1998, 40 years later, production of HTP at the Warrington site continued, primarily for on-site captive use in the production of chemical intermediates.

During the 1990s, only limited drum quantities of 85% HTP were provided by Solvay Interlox to aerospace and defense-related companies for propulsion applications. During this period, the demand for HTP in the US was, in practice, very small, which explains the hesitation to step up commercial HTP production in the US. Historically, in the long, distant past when the Mercury project was the first manned US space program, US demand was more significant, and both the Shell Chemical Company and the FMC Corporation were producers of 90% H_2O_2 at that time, the latter company also producing some 98% H_2O_2 for a short period of time. Shell's hydrogen peroxide business was ultimately acquired by Interlox, and FMC ceased its production of HTP in the early to mid-1980s.

A new, so-called "high-productivity/high-yield" process, based on a mixture of isomers of 2-amyl anthraquinone, has been developed by Solvay. In 2008, Solvay announced the construction of a "mega-scale" single-train plant in Zandvliet (Belgium). The plant has an annual production capacity more than twice that of the world's next-largest single-train plant. An even larger plant was commissioned in 2011 by a joint venture of Solvay and Dow in Map Ta Phut (Thailand). This plant has a projected production capacity of 330000 tons of hydrogen peroxide per year (number based on 100% H_2O_2 concentration) [104].

2.4.3.3 History of Shell Hydrogen Peroxide Process with 2-Propanol

Another autoxidation process, based on the oxidation of 2-propanol (IPA), was developed by Shell Chemicals. The process was employed by Shell in its 15000 metric tons per annum facility at Norco, Louisiana, between 1957 and 1980. The oxidation of 2-propanol in the liquid phase with oxygen does not require a special catalyst, because it is catalyzed by a small amount of hydrogen peroxide, which is added to the feed stream as a seed in order to shorten the induction phase. The acetone coproduct can either be sold or hydrogenated back to isopropyl alcohol for recycling. Several plants operating on this process were built in the former Soviet Union, which have been operating since 1968 and 1972. Regarding the use of IPA in this process, one must remember that efforts to recycle IPA that was used as an industrial cleaning solvent by redistilling it risk explosions caused by accumulation of organic peroxides in the distillation residue. Solvent grade IPA contains a substantial amount of acetone, one of the autoxidation products. Acetone and hydrogen peroxide also react to form an explosive substance that can crystallize on the walls of cold parts of the equipment.

A similar liquid phase oxidation process of isopropyl alcohol with molecular oxygen has been used in the USSR (Russia) for quite some time, even after the US chemical industry quit using it [105]. Russia is the main user of hydrogen peroxide as a monopropellant in its Soyuz crewed space capsules and as a gas generant to drive the propellant pumps in the Soyuz launch vehicle. The method of hydrogen peroxide production by isopropyl alcohol autoxidation is more environmentally friendly than the anthraquinone method. The only waste products are non-toxic gases and acetone, which can be hydrogenated back to isopropyl alcohol. This method is widely used in Russia for the hydrogen peroxide that is concentrated to become a rocket propellant. Mixtures of air and isopropyl alcohol or hydrogen peroxide and isopropyl alcohol encountered during this process are more explosive than anthraquinone autoxidation intermediates [106]. The product of the isopropyl alcohol autoxidation production method is a 30–40% hydrogen peroxide solution that needs to be further concentrated to make rocket-grade hydrogen peroxide (RGHP). This aqueous solution still contains impurities such as acetic acid, acetone, isopropyl alcohol, acetone peroxide, and heavy metal ions. Organic impurities contents in the product are limited by Russian specifications to 0.55–0.7 mass-%, containing 0.2–0.3 g/dm³ of isopropanol, 6–8 g/dm³ of acetone, and 6–8 g/dm³ acetic acid [107–109].

2.4.3.4 History of Lyondell Hydrogen Peroxide Production

Another version of the oxidation of a secondary alcohol to hydrogen peroxide and a ketone is the process developed by Lyondell (ARCO) Chemical, using methylbenzyl alcohol as a hydrogen carrier. This material is an intermediate in a propylene oxide/styrene process. The oxidation coproduct, acetophenone, is hydrogenated back to methylbenzyl alcohol in a step that is a part of the Lyondell styrene technology.

In December 2007, the Lyondell Chemical Company and Basell completed their merger to create LyondellBasell, one of the world's largest polymers, chemicals, and

fuels companies. They make propylene oxide and mono-, di-, and tripropylene glycol by a peroxide process. Instead of isolating hydrogen peroxide from a direct synthesis from the elements catalytic process, the hydrogen peroxide is used in situ to oxidize propylene to propylene oxide in a reactor with a suspension of a catalyst slurry fed with a mixture of propylene, hydrogen, and oxygen (US Patents 6710194, 6500311, and 7501532).

Different trade names have been registered by H_2O_2 manufacturers and distributors, such as

- Oxypure™ by FMC
- Perhydrol® by Merck
- Hyprox™ by Arkema
- Propulse™ by Evonik (former Degussa)
- Interlox® by Solvay

It may be of interest to look at the historical evolution of installed production capacity for hydrogen peroxide. This rapid growth was caused mostly by the realization that the use of chlorine and (to a lesser extent) chlorine dioxide in the paper and pulp industry would leave undesirable byproducts in chlorine-bleached paper and caused many persistent pollutants (dioxin, PCB) to be discharged with the wastewater. In many of these applications, chlorine has been replaced by hydrogen peroxide. To a lesser extent, hydrogen peroxide also competes with chlorine in the use of chlorine and hypochlorite as a disinfectant in water treatment.

The electrolysis process generates hydrogen gas as a byproduct that would have to be flared off or collected for other uses. It is possible to combine the electrolytic and chemical production of hydrogen peroxide by the anthraquinone reduction/oxidation route at the same locale. The hydrogen would then be used for reduction of anthraquinone.

A more recent process is the direct synthesis of hydrogen peroxide from the elements on a nanocatalyst.

2.4.3.5 History of FMC/Becco Hydrogen Peroxide Production

In 1958, FMC formed joint ventures in Japan and Brazil to manufacture hydrogen peroxide. In 1978, FMC became the world's second largest producer of hydrogen peroxide. In 1990, FMC opened a new hydrogen peroxide plant in Prince George, British Columbia, to serve western Canada. In 1994, FMC built a hydrogen peroxide plant in Delfzijl, The Netherlands.

In 2010, FMC announced realignment of hydrogen peroxide manufacturing operations at Bayport, Texas. The key elements of the improvements at the Bayport site included upgrades to increase production of high-purity grades of hydrogen peroxide in support of growing specialty applications, especially those with ultra-pure quality requirements and mothballing of certain unit operations effectively reducing the overall capacity of standard grade hydrogen peroxide by approximately 90 million pounds

per year, driven by significantly reduced demand from the pulp and paper industry, historically a large volume consumer of hydrogen peroxide. As of 2012, FMC still offers hydrogen peroxide solutions in concentrations ranging from 3 to 90% HTP [110].

2.4.3.6 Summary of Hydrogen Peroxide Production in the US

There are essentially six major producers in the United States that produce H_2O_2 . DuPont has withdrawn from the hydrogen peroxide production. In 1998, the Memphis, TX, plant was sold to Elf Atochem, the Canada (Gibbons, Alberta) and New Zealand plants were sold to Degussa, and the Maitland (Canada, Ontario) plant was sold to Evonik.

2.4.3.7 Summary of Hydrogen Peroxide Production Outside the US

High-purity hydrogen peroxide in concentrations usually not exceeding 70% is produced in many other countries, including mainland China [111]. While actively gearing up to significantly expand domestic hydrogen peroxide production, China is cautiously observing capacity developments in other countries [112, 113].

As of 2011, one of the largest international hydrogen peroxide producers, Evonik, had an annual production capacity of approximately 600000 tons of hydrogen peroxide and was building a new facility for a further 230000 tons per year in Jilin (China) [114]. There, H_2O_2 will be used as an environmentally friendly oxidant for the direct chemical synthesis of propylene oxide. Evonik production facilities already exist in Germany, Belgium, Austria, the United States, Canada, Brazil, Korea, Indonesia, New Zealand, and South Africa. H_2O_2 is employed for a very wide range of applications. The largest quantities are still used in pulp bleaching and in manufacturing laundry detergent powders and liquids.

2.4.4 New Developments for the Production of Hydrogen Peroxide

New processes to produce hydrogen peroxide directly from the elements have been of interest for many years [29, 115]. Water can be produced from the elements without too many problems but making hydrogen peroxide from the elements is a different story. The problem with the direct synthesis process is that, due to the laws of thermodynamics, the reaction of hydrogen with oxygen favors the production of water. Hydrogen peroxide is an intermediate in this reaction that decomposes just as fast as it is formed, unless the reaction is quenched or diverted. It had been recognized for some time that a finely dispersed catalyst is beneficial in promoting selectivity to hydrogen peroxide, but, while selectivity was improved, it was still not sufficiently high to permit commercial development of the process [116]. Nanometer-size phase-controlled noble metal crystal particles (gold-palladium nanoparticles) on a carbon support can improve the yield of hydrogen peroxide in water or liquid carbon dioxide as the solvent. This process results in low concentrations of hydrogen peroxide

(about 5–10 mass-% versus about 40 mass-% H_2O_2 obtainable by the anthraquinone process).

An electrochemical process to produce alkaline hydrogen peroxide has been developed by H-D Tech Inc., formerly a joint venture of Huron Technologies Inc. and Dow Chemical of Canada, but now wholly owned by Dow. The process employs a monopolar cell to achieve an electrolytic reduction of oxygen in a dilute sodium hydroxide solution.

2.5 Other Methods for Formation of Hydrogen Peroxide

There are many other methods how hydrogen peroxide may form from water or from the elements, but these methods may not necessarily be industrially lucrative. These methods are listed here only for comparison or in the remote chance that they may become competitive under a special set of circumstances, for instance on the surface of the moon or another planet. Naturally occurring hydrogen peroxide forms by one of these mechanisms. Natural occurrence of hydrogen peroxide was already described in Section 5.2.1, but the mechanisms leading to the formation of H_2O_2 under those conditions are discussed here. In many cases, the same mechanism also plays a role in the decomposition of H_2O_2 , so that under many conditions, a stationary concentration of H_2O_2 is maintained.

2.5.1 Formation of Hydrogen Peroxide from the Elements

2.5.1.1 Direct Combustion Methods

Some H_2O_2 is formed during the combustion of hydrogen in oxygen-rich flames. If the flame from a lean O_2/H_2 flame is directed at an ice cube, the high-temperature composition in the flame is quenched, and H_2O_2 is preserved from further decomposition while the reaction products cool off. Theoretically, a rocket taking off with LOX/ LH_2 propellants could be spewing H_2O_2 in its exhaust plume, but these engines typically operate on the fuel-rich side of the stoichiometric composition, so the formation of H_2O_2 under those conditions is less likely. Automobiles operating on gaseous hydrogen in air typically operate with lean mixtures, and it is possible that H_2O_2 can be found in the exhaust of those machines.

Hydrogen peroxide is an intermediate in the oxygen/hydrogen reaction, but it decomposes just as fast as it forms [117].

It is generally assumed that combustion of hydrogen-air mixture in a power producing device, such as an internal combustion engine, should lead to clean exhaust (except for the emission of traces of nitric oxide). However, an experimental study with a hydrogen-fueled engine indicated that another pollutant, hydrogen peroxide, may be emitted in the exhaust gases in concentrations as high as 220 ppm [118]. A model

for the combustion of hydrogen-air mixtures was derived, which included reactions leading to H_2O_2 .

2.5.1.2 Isothermal, Non-combustion Reactions

Passing oxygen/hydrogen gas mixtures with compositions between the second and third explosion limit through a heated zone at 773–873 K (500–600 °C) results in the formation of traces of hydrogen peroxide. The production of hydrogen peroxide in hydrogen-oxygen mixtures under conditions between the second and third explosion limits was studied using a flow method in an isothermal reactor at 839 K (566 °C) [119]. Hydrogen and oxygen were dried, and their flow rates measured on flow-meters. The gases were mixed and passed through a narrow-bore tube into a cylindrical silica reaction vessel, which they entered tangentially at the bottom. They flowed out of the reaction vessel from the center of the top via a 2-mm inner diameter (ID) tube into two consecutive U-tube cold traps cooled in liquid oxygen in which water and hydrogen peroxide were frozen out and analyzed. The residence time in the reactor was 2 to 10 s. Unwanted explosions sometimes took place in the vessel, potentially caused by catalytic walls.

2.5.1.3 Direct Synthesis of Hydrogen Peroxide from the Elements by Catalytic Methods

Instead of operating a flame at high temperature, O_2 and H_2 can be combined to H_2O_2 on a catalyst during catalytic non-combustion reactions at moderate temperatures, usually in an inert process solvent to maintain constant temperature and good heat transfer, typically with an excess of O_2 . These methods would have the advantage that they would produce an organics-free hydrogen peroxide that is better suited for rocket applications than hydrogen peroxide produced by the anthraquinone or 2-propanol air oxidation methods. One of the first catalysts tested successfully for this application was a palladium catalyst [120–122].

A porous metal phosphonate compound $\text{Zr}_2(\text{PO}_4)(\text{O}_3\text{PCH}_2\text{CH}_2\text{-bipyridinium-CH}_2\text{CH}_2\text{PO}_3)\text{X}_3 \cdot 3\text{H}_2\text{O}$ (X = halide) allows the direct production of hydrogen peroxide from hydrogen and oxygen [123]. Platinum and palladium colloids can be incorporated into the structure by ion-exchanging the free halide X with a solution of K_2MCl_4 (M = Pd or Pt) followed by hydrogen reduction. These materials selectively reduce oxygen to hydrogen peroxide. Treatment of aqueous suspensions of these porous catalysts with H_2 and O_2 gases at atmospheric pressure leads to H_2O_2 solutions with concentrations as high as 0.21 M. Reactions carried out at higher pressures lead to even higher concentrations of H_2O_2 . The yield of H_2O_2 based on H_2 consumed was estimated at 40%.

For the direct synthesis of H_2O_2 from the elements at low temperature (275 K) the Au-Pd catalysts performed significantly better than the pure Pd/ TiO_2 or Au/ TiO_2 materials [124]. Au-Pd particles had a core-shell structure, with Pd concentrated on the

surface. The highest yields of H_2O_2 were observed with uncalcined catalysts, but these were unstable, losing active metals during use. In contrast, samples calcined at 673 K were stable and could be reused several times without loss of performance. Strangely, these catalysts exhibited low activity for CO oxidation at 298 K but conversely, catalysts effective for low-temperature CO oxidation were inactive for H_2 oxidation to H_2O_2 . This anti-correlation was difficult to explain.

Palladium catalysts supported on Cl^- , F^- or Br^- -doped zirconia were tested for the direct synthesis of hydrogen peroxide under very mild (101 kPa and 293 K) and non-explosive conditions [125]. The catalysts were characterized by thermogravimetric/differential scanning calorimetry analysis, N_2 physisorption, and temperature-programmed reduction before and after catalytic tests to investigate the oxidation state of the metal. The best catalytic results were observed in methanol as a solvent, using H_2/O_2 non-explosive mixtures containing a large excess of oxygen and using a sulfate-doped zirconia catalyst. Surface-oxidized PdO catalysts showed high catalytic activity and the highest selectivity.

Bimetallic Pd-Pt and Pd-Au samples supported on sulfated zirconia were successfully tested for the direct synthesis of H_2O_2 under very mild conditions (101 kPa and 293 K) and outside the explosion range [126]. The effect of the addition of Pt to Pd in enhancing the yield of H_2O_2 was sensitive to the Pt amount; only by using a low Pt content was it possible to improve H_2O_2 selectivity (from 55 to 70%) and productivity with respect to the monometallic sample. The addition of gold in 1:1 amount to palladium improved both the productivity and even more the selectivity of the process, producing a H_2O_2 concentration already useful for industrial applications and maintaining a stable selectivity (62%) after 12 h of time on-stream.

2.5.1.4 Formation of Hydrogen Peroxide from Water

Water, water everywhere (at least on this planet), and under the right conditions with additional energy input in the form of ionizing radiation, ultraviolet light or electric discharges, with or without dioxygen available from ambient air, hydrogen peroxide will form from water in the solid, liquid, or vapor state. The natural occurrence of hydrogen peroxide is ascribed to these reactions, and observations where H_2O_2 can be found naturally are described in Section 2.1. Hydrogen peroxide has been detected in some unexpected, exotic places. This may have implications for extraterrestrial resource utilization, where crewed stations on other planets can harvest H_2O_2 as a source of water, oxygen, and energy.

The same energy input that allows formation of hydrogen peroxide from water will also cause some of the freshly formed H_2O_2 (or D_2O_2) to decompose in reversal of the reactions that led to its formation. The radiolysis and plasma decomposition of H_2O_2 is described in detail in Sections 4.11.2 and 4.11.3. There is some overlap between the experiments investigating the decomposition of H_2O_2 and the studies of the formation of H_2O_2 from water and oxygen.

2.5.1.5 Ultraviolet Radiation

The formation of H_2O_2 by UV illumination of water ice is a mechanism of H_2O_2 formation that may prevail on a large scale on any celestial body that has accumulated an ice crust, such as Jupiter's moon Europa or several of the Saturnian satellites.

H_2O_2 can be photolytically produced (and destroyed) on a water ice surface by illumination with 157 nm UV at 90 K [127]. H_2O_2 thus formed can then be characterized by photodissociation with 300–350 nm UV leading to the production of gaseous OH radicals that can be directly monitored using resonance-enhanced multi-photon ionization. Surface defects produced by HCl deposition on the water ice lead to a higher production rate of H_2O_2 in the 157 nm photoirradiation of water ice.

Even whatever little UV is in sunlight on the surface of Earth (enough to give one a sunburn and cause skin cancer) is sufficient to cause H_2O_2 formation in surface water [128]. A rapid increase in the concentration of hydrogen peroxide was observed when samples of natural surface and groundwater from various locations in the United States were exposed to sunlight [129]. Hydrogen peroxide is photochemically generated from organic constituents present in water. Humic materials (some containing aromatic phenols and hydroquinones) are believed to be the primary agent producing the peroxide. Studies with superoxide dismutase suggest that the superoxide anion may be a precursor of peroxide. The photochemical accumulation rate of H_2O_2 in sunlight was measured for several surface waters and pond waters and was found to be 2.7×10^{-7} to $48 \times 10^{-7} \text{ mol L}^{-1} \text{ h}^{-1}$ in waters containing from 0.53 to 18 mg L^{-1} dissolved organic carbon (DOC), respectively. These rates were determined in midday sunlight, 0.4 W m^{-2} (295–385 nm) at a latitude of 24.3° N . Apparent quantum yields decreased with increasing wavelength, from 10^{-3} in the near ultraviolet to 10^{-4} in the visible spectral range. Freshwater in the southeastern United States has a natural H_2O_2 content of $0.9\text{--}3.2 \times 10^{-7} \text{ mol/L}$, which upon more intense illumination can be bumped up to $6\text{--}70 \times 10^{-7} \text{ mol/L}$. Seawater in the Biscayne Bay in Florida contains $0.14\text{--}2.1 \times 10^{-7} \text{ mol/L}$.

2.5.1.6 Photocatalytic Synthesis Methods

Light photons (even less energetic light in the visible range) impinging on solid state catalysts can enable them to convert water (liquid or vapor) to hydrogen peroxide.

A new method for the photochemical synthesis of hydrogen peroxide was discovered when in the course of investigations on the photochemical production of hydrogen peroxide in the liquid phase, it was noticed that finely ground photocatalyst became loaded with H_2O_2 when it was allowed to stand exposed to room lights for long periods [130]. This led to the development of a gas-phase photochemical synthesis method for hydrogen peroxide photocatalyzed on solids.

Achieving photosynthetic splitting of water to form dihydrogen and dioxygen as a means of solar energy conversion and storage has long been the holy grail of photochemists and has still not achieved industrial maturity. A variation of this push for water splitting is the attempt to split water into hydrogen and hydrogen peroxide actu-

ally would be even better because hydrogen peroxide is easier to store than oxygen gas [131]. A system like this might work on the moon or on Mars (only after more water is found there). The electrolytic synthesis of hydrogen and hydrogen peroxide from water has been demonstrated. One such system consisted of a hydrogen electrode with platinum mesh, a hydrogen peroxide electrode with carbon material, and an electrolyte with Nafion[®].

2.5.1.7 Catalytic Methods

H₂O₂ can be synthesized from O₂ and H₂O in the presence of a complex such as (PPh₃)₂PdO₂ with equimolar proportions of H₂O₂ and CO₂ being formed [132]. The reaction proceeds at room temperature in a stirred, two-phase water-dichloromethane system.

2.5.1.8 Neutron Radiation

Thousands of tons of heavy water circulate in heavy-water moderated nuclear power plants, and radiolysis of D₂O in close proximity to nuclear reactors forms noticeable quantities of D₂O₂. Spent nuclear reactor fuel rods are stored in large pools filled with natural water (H₂O with a natural amount of D₂O) while they cool off and are waiting for reprocessing. Under all these conditions, hydrogen peroxide forms and greatly changes the corrosive behavior of the water.

2.5.1.9 X-Ray Irradiation

X-rays penetrating through water (or living tissue) in the presence of oxygen cause the formation of traces of hydrogen peroxide. Hydrogen peroxide and the free radicals associated with its formation and decay may be a contributing cause to radiation damage suffered in living tissue. Each time we undergo an X-ray for the diagnosis of a medical condition, there may be a “puddle” of hydrogen peroxide forming in our bodies.

Irradiation with X-rays produced no chemical change in air-free water. With oxygen present, hydrogen peroxide was formed due to a primary activation of the water [133]. The initial production of hydrogen peroxide was independent of the oxygen pressure, from 40 to 700 mm Hg but was dependent on the hydrogen ion concentration.

Hydrogen peroxide yields obtained by the action of 150-keV X-radiation on air-saturated solutions of KBr were strongly pH dependent [134]. There are several hypotheses on the various mechanisms for the formation of hydrogen peroxide by these reactions.

2.5.1.10 Gamma Radiation

A better understanding of the effects of gamma radiation on peroxide formation in water is needed to predict the abundance of hydrogen peroxide in extraterrestrial ice on planets, their moons, and on comets. The destructive power of gamma radiation in living tissue may also involve free hydroxyl radicals. Recombination of OH radicals

formed by γ -radiolysis of water forms hydrogen peroxide [135]. When air-saturated KBr solutions were subjected to cobalt γ -radiation, the initial yield of H_2O_2 was dependent upon the concentration of KBr. The yield of H_2O_2 (formed by the combination of OH radicals in regions of high ionization density) was 0.75 molecule per 100 eV in sulfuric acid solution at a pH of 2 and 0.78 molecule per 100 eV in 0.8-N sulfuric acid [136, 137].

Pure, oxygen-saturated water was irradiated with ^{60}Co gamma radiation [138]. At low doses, the G-factor (H_2O_2) was 2.6. At doses greater than 2000 rad, the G-factor (H_2O_2) was 1.33. Over the entire dose interval $G(\text{H}_2)$ was constant at 0.17. The G values of 1.33 and 0.17 agreed with published data. The results were compared with the generally accepted mechanism for the radiolysis of oxygen-saturated water and the conclusion was reached that this mechanism was in error, at least in the low dose range. An alternate mechanism was proposed to account for the experimental results where H_2O^+ and e^- are proposed as the primary species in the radiolysis of water.

The concentration of hydrogen peroxide formed in thawed γ -irradiated air-saturated ice as a function of dose did not fit a linear plot [48]. By extrapolation of an empirical equation to very low dose, $G \text{ H}_2\text{O}_2$ was evaluated to be 0.32.

Spent nuclear reactor fuel rods are stored in large pools filled with water while they cool off and are waiting for reprocessing. Under all these conditions, exposed to neutron-, α -, β -, and γ -radiation, hydrogen peroxide forms and adversely changes the corrosive behavior of the water. The water may also contain suspended solids, aluminum oxide and zirconium oxide particles that have corroded from the cladding of the fuel elements. This information is important for the safety of an operating nuclear power plant or of a repository for spent nuclear fuel.

Hydrogen peroxide is the main stable oxidizing species formed in the radiolysis of water, and its long-term yield was found to be dependent on several variables. The yields of hydrogen peroxide in the radiolysis of aqueous solutions of acrylamide, bromide, nitrate, and air in the pH range of 1–13 were measured [139]. Experiments with γ -irradiation showed that the primary yields of hydrogen peroxide were nearly independent of pH in the range of 2–12. The G-factor (expressed in mol/100 eV) decreased from 0.71 to 0.5 if the pH was increased from 1 to 12. Slightly higher primary yields were suggested at very low pH, in particular when O_2 was present, while the yields decreased at very high pH. In addition to γ -radiation, other irradiations were performed with 5-MeV H ions, 5-MeV He ions, and 10-MeV C ions to evaluate the intratrack and homogeneous kinetic contributions to H_2O_2 formation with different ions. Many of the same trends in hydrogen peroxide yields with pH observed with γ -irradiations are observed with irradiation by the heavy ions.

Suspended alumina or zirconia particles, corrosion products from deteriorating nuclear reactor fuel elements, will alter the rates of formation and decomposition of H_2O_2 in water-filled pools where spent fuel rods are in temporary storage, awaiting reprocessing. Therefore, the yields of H_2O_2 in aqueous alumina slurries in the pH range of 1–13 with various amounts of added Al_2O_3 nanoparticles were determined [140]. The

addition of Al_2O_3 generally decreased H_2O_2 yields at all pH values within this range in the γ radiolysis of both deaerated and aerated slurries, except at pH above 11.

The first-order and second-order rate constants for the decomposition of H_2O_2 in the presence of ZrO_2 slurries at $T = 298\text{ K}$ produced the values

$$k_1 = (6.15 \pm 0.04) \times 10^{-5} \text{ s}^{-1}$$

$$k_2 = (2.39 \pm 0.09) \times 10^{-10} \text{ mol s}^{-1}.$$

The activation energy for the reaction was obtained in the temperature interval 294–353 K from the dependency of the reaction first-order rate constant with temperature and was $E_a = 33 \pm 1.0 \text{ kJ mol}^{-1}$ [141].

In addition to alumina slurries, the adsorption and decomposition of H_2O_2 on nano- and micrometer-sized particles of other ceramic metal oxides, ZrO_2 , TiO_2 , and Y_2O_3 were characterized by measuring the reaction rate constants, the Arrhenius activation energies, and the activation enthalpies for the processes of adsorption and decomposition of H_2O_2 [142]. The experimentally obtained enthalpies of activation for the decomposition of H_2O_2 catalyzed by these materials are $30 \pm 1 \text{ kJ/mol}$ for ZrO_2 , $34 \pm 1 \text{ kJ/mol}$ for TiO_2 , and $44 \pm 5 \text{ kJ/mol}$ for Y_2O_3 . Other ceramic oxides studied included SiO_2 , Al_2O_3 , TiO_2 , CeO_2 , and ZrO_2 [143].

2.5.1.11 Microwave Plasma Discharge

Water vapor flowing at low pressure through the resonant cavity of a microwave oven will glow and become ionized. This method of exciting a glow discharge is also called “electrodeless discharge”. The formation of hydrogen peroxide by dissociation of water vapor in an electric discharge was studied for the purpose of preparing sizeable quantities of deuterium peroxide D_2O_2 [144]. The apparatus featured a large pumping capacity and a high-frequency electrodeless discharge (20 MHz). The dissociated gas went directly into a large liquid air cooled trap where it formed a glassy deposit. On warming, this deposit first evolved hydrogen, then at about 158 K (-115°C) some oxygen. Solutions of hydrogen peroxide with concentrations of up to 56% were obtained. With $\frac{1}{2} \text{ kW}$ dissipated in the discharge, an optimum yield of 15 g of 50% peroxide per hour was reached.

Similar results can be obtained with glow discharges in a tube filled with water vapor at low pressure and carrying electrodes with electrically conductive feedthroughs at both ends, similar to a neon tube for advertising [145].

At low flow rates ($0.7\text{--}2.8 \text{ mmol h}^{-1}$) and long residence times (2.3–8.5 s), nearly 60% of the input water vapor was decomposed by a 13.56-MHz high-frequency plasma discharge [146]. Downstream of the glow discharge a trap cooled by liquid nitrogen collected nearly constant yields of H_2O_2 . The decomposition was representable by the equation

The overall rate of decomposition was found to depend on the absorbed power density. Heating the rf plasma and its spatial afterglow from 298 to 873 K (25 to 600 °C) did not significantly change the percent decomposition of H_2O and the formation of H_2O_2 .

2.6 Methods for Concentrating Hydrogen Peroxide

In many cases, the concentration of hydrogen peroxide available in the open market may not be sufficient for the intended rocket application. Several organizations have developed methods for concentrating H_2O_2 to higher concentrations needed for rocket applications. Due to the explosion potential, this must be done extremely carefully and only with the proper equipment and adequate safety precautions.

There are now high-purity grades (“electronic grade”) of H_2O_2 solutions available for the etching of semiconductors, which do not contain any stabilizers and are suitable for concentrating when the unwanted accumulation of stabilizer is expected to interfere with the intended application.

2.6.1 Evaporation and Distillation Methods

Because water and hydrogen peroxide do not form an azeotrope and because the boiling points are far apart (H_2O : 373 K = 100 °C; H_2O_2 : 423.3 K = 150.2 °C), separation by evaporation and distillation is relatively simple. Up to a concentration of 65% H_2O_2 , distillation can even be done at atmospheric pressure. Beyond 65% H_2O_2 , the process becomes dangerous and needs to be done at reduced pressure [147, 148].

In the early years of hydrogen peroxide evaluation as a rocket propellant, a distillation column for the fractionation of the hydrogen peroxide/water system was designed, built, and tested [149]. With a feed rate of about 0.03 kg/min. of material containing 35 mass-% hydrogen peroxide, a product containing 82.6 mass-% hydrogen peroxide was obtained. About 76% of the input hydrogen peroxide was contained in the product, and a total of about 91% of the input hydrogen peroxide was recovered in the sum of the product and in the distillate.

At NASA Stennis Space Center a skid-mounted modular concentration facility was once set up by Degussa (as of 2007, this company is now called Evonik), which was capable of producing Propulse® 980. An external view of this facility is shown in Figure 1.

The Propulse™ 980 unit was a transportable, modular processing plant that enriched aerospace grade hydrogen peroxide from 90 to 98% final concentration [150]. The unit was developed by Degussa, in cooperation with Orbital Sciences, NASA Marshall Space Center, and NASA Stennis Space Center. The system was a self-contained unit that housed all of the process equipment, instrumentation and controls to perform the concentrating operation nearly autonomously. It was designed to produce non-bulk quantities of 98% hydrogen peroxide. The unit was first tested, then dis-

Figure 1: Hydrogen peroxide concentrating facility once located at NASA Stennis Space Center. (Photo credit: NASA.)

assembled at the Degussa plant in Theodore, AL, transported to NASA Stennis Space Center, reassembled, and subjected to a series of checkout tests to verify that all design objectives had been met. The production goal for the enrichment unit was to produce a minimum of 1000 pounds of 96% H_2O_2 product per day safely and automatically.

In addition to industrial methods for concentrating hydrogen peroxide to obtain rocket-grade high-test peroxide, there have been several methods described in the literature that were used by academic institutions or amateurs that wanted HTP free from stabilizers or could not afford to obtain commercial quantities of HTP delivered in drums or tank cars.

The primitive and not advisable method described in [151, 152] used open-air evaporation of food-grade 35% H_2O_2 containing both stannate and phosphate stabilizers in 1-L glass beakers on hot plates in a fume hood. Over a period of 18 h, the residue reached a concentration of 85% and about one-fourth of the H_2O_2 was lost with the water vapor. Not only H_2O_2 , but also all contaminants and stabilizers were concentrated in this way in the residue, resulting in an intermediate product with ~80 ppm of impurities. This material was then distilled in a Rotavapor from a warm water bath not exceeding 323 K (50 °C) under vacuum at 1.3 kPa (10 mm Hg). Table 1 gives a comparison of analysis results of the commercial food grade HP and the concentrated and distilled product.

In tests at Purdue University [153], concentrating of HP starting with 50% supplied by Interlox was performed by remote heating in 4000-mL Erlenmeyer flasks until a batch of 4 to 5 gallons of 85% H_2O_2 was gathered. This was done to minimize batch-to-batch variations of fluid physical properties on the fired motor data. Concentrating HP by this method of course also concentrated the stabilizer and all other unwanted contaminants in the original fluid. For concentrating HP from 50 to 85%, the boiling began around 380 K (225 °F) and was terminated at 411 K (280 °F). At such an elevated fluid temperature, only glass containers may be used to avoid spontaneous decomposition. This method may only be used with highly stabilized HP because thermal decomposition takes place in unstabilized HP above 70% concentration at that temperature. In some instances, the energy from a vapor-phase detonation in the space

Table 1: Comparison of analysis results of concentrated and distilled hydrogen peroxide.

Organization Constituent	Unit	Purchased, as received	Sandia Livermore Concentrated and distilled
H ₂ O ₂	% by mass	35	85
Ca	mg/kg	0.01	0.03
K	mg/kg	2.6	<0.1
Na	mg/kg	1.2	<0.1
P	mg/kg	3.9	<0.5
S	mg/kg	0.04	0.05
Sn	mg/kg	3.7	0.08
Ammonium	mg/L	1.13	<0.4

Data source: [151, 152]

above the boiling surface initiated a thermal decomposition wave (boil-off) in the liquid during this research program. While these vapor-phase detonations were not terribly energetic (many of them sounded like a small firecracker exploding), some were strong enough to crack/shatter the flasks used for boiling.

Preparation of electronic grade high-concentration hydrogen peroxide requires operating with an all-fluoropolymer apparatus avoiding contact of the liquid with glass or other contaminating surfaces, maintaining the pressure in the evaporator below 100 mm Hg, maintaining the vapor phase concentration of H₂O₂ in the evaporator below 26 mol-% by connecting to a dynamic vacuum pump (water aspirator), and maintaining an inert purge gas flow [154].

Another vacuum concentrating process operates at a vacuum of at least 10 mm Hg and consists of two cojoined but separable pieces of equipment: a distillation column at the top and a falling film evaporator at the bottom. The bottoms of the distillation column are fed into the falling film evaporator, giving a solution with at least 90% H₂O₂ [155]. This once-through process avoids the accumulation of concentrated product in the still.

While the concentrating methods described by Tillotson or Bloomfield are not economical because their operation requires use of vacuum pumps, the method patented by Carden operates at atmospheric pressure circulating compressed, heated, dry (dew point -40 to -75 °C) air countercurrent in a mass transfer device (bubble cap column, packed column, air stripping column or falling film evaporator) and then through a fluid (air) dryer [156]. This method was later adopted by Beal Aerospace Corp. for a 5-ton-per-day hydrogen peroxide concentrator at McGregor, TX.

Stabilizers and impurities may accumulate in the pot residue of H₂O₂ concentrating distillation units and form a sediment. The problem of sediment formation in the

concentrating process of hydrogen peroxide, the analysis of sedimentary deposits, and preventive measures were described [157].

A microstructured falling film evaporator made from AlMg₃ was used to evaporate 50 mass-% aqueous hydrogen peroxide solutions in a concentrator at elevated temperatures (about 403 K = 130 °C) [158]. After an initial self-passivation procedure under operating conditions, the relative decomposition related to the evaporated amount could be reduced to values of about 10%. From the experimental results, it was concluded that the decomposition occurred mainly in the liquid phase during evaporation and not in the vapor phase by contacting the non-wetted surfaces of the evaporator and pipes. At an operation temperature of 403 K = 130 °C, 10 vol.-% of hydrogen peroxide in the vapor could be reached, which almost corresponded to the vapor/liquid equilibrium at the top of the evaporator. See also [159–161].

The main hazard during concentrating during a four-stage distillation of hydrogen peroxide that was made by the isopropyl alcohol autoxidation process is the potential accumulation of triacetone triperoxide, a highly explosive material [107]. The heat of explosion of triacetone triperoxide is 2803 kJ/kg, which is 88% of TNT equivalent. The velocity of detonation triacetone triperoxide is 5300 m/s at a density of 1.2 g/cm³ and about 1430 m/s at 0.47 g/cm³. The content of acetone and isopropyl alcohol impurities should be kept below 0.02 mass-% in order to provide a good quality product and maintain appropriate safety of the concentrator. Another explosive byproduct is peracetic acid.

2.6.2 Fractional Crystallization and Zone Melting Methods

Concentration of hydrogen peroxide by fractional crystallization is based on a thorough understanding of the solid-liquid phase diagram (see Figure 2 and 3) for the system hydrogen peroxide-water. Figure 2 and 3 show the depression of the freezing point of each component by addition of the other component and two eutectic points. For concentrating and purifying the 70% H₂O₂ liquid feed stock is chilled to 218 K (–55 °C), which forms a two-phase system consisting of solid hydrogen peroxide and a 62% H₂O₂ concentration liquid. Because the solid hydrogen peroxide slush occludes significant amounts of mother liquor, it gets centrifuged and separated before thawing. The majority of impurities remains in the liquid rather than in the solid. For reuse the 62% H₂O₂ liquid needs to be distilled to 70%. Even though this process is safer than a distillation, nobody used it on a commercial scale. The Propulse 980™ unit at NASA Stennis is only a pilot plant scale. The Propulse 980™ portable concentrating unit developed by Degussa for NASA uses a fractional crystallization method. The feedstock (90%) is separated into 80% H₂O₂ byproduct (“mother liquor”) and the 98% finished product. The process yield is about 50%. Stabilizers and contaminants in feedstock are greatly reduced in the finished product. Production of >92% H₂O₂ should always be done by fractional crystallization and not by distillation.

2.6.3 Membrane Separation Methods

Semipermeable membranes can selectively allow passage of water, leaving more concentrated H_2O_2 behind.

Semipermeable membranes capable of separating a H_2O_2 solution from a sweep gas or permeate (water) are selective due to the preferred permeability of water over the permeability of H_2O_2 , thereby concentrating the H_2O_2 solution through the removal of water through the membrane to the permeate. Membranes can be made of PTFE and a perfluorinated polysulfone copolymer having sulfonic acid functional groups [162]. The membrane system was designed so that the hydrogen peroxide solution was on one side of the membrane and dry sweep air was on the other side. The water capacity of the sweep air was increased by increasing the temperature, but the temperature was kept below the spontaneous decomposition temperature of hydrogen peroxide. This method would provide HTP at the point of use where commercial grade 70% hydrogen peroxide can be enriched to 85%. In this process, HTP is not exposed to reactive surfaces. As of 2012, NASA was offering the use of this patent to potential licensees for industrial use.

Instead of simple air stripping (which has problems of liquid entrainment), the mixture of sulfuric acid, H_2O_2 and water obtained after electro-oxidation of sulfuric acid and hydrolysis of persulfuric acid can be separated by passing a hot carrier gas through the mixture and separating the vapor by a hydrophobic membrane [163]. The acid is concentrated in the residue and returned to the electrolyzer.

Pervaporative separation of corrosive liquids is challenging in terms of selecting a suitable polymeric membrane that can withstand the harsh environment especially when attempting to concentrate an aqueous solution of an oxidizing liquid such as hydrogen peroxide. The choice of membrane material is limited to fluoropolymers and perfluoropolymers. Perfluorodimethyldioxole-tetrafluoroethylene (PDD-TFE) copolymer membranes (CMS-3 and CMS-7) were used to concentrate hydrogen peroxide from its aqueous solutions [164]. The feed solution composition was varied between 4 and 40 mass-% H_2O_2 , and the process was operated at 298, 303, and 308 K (25, 30, and 35°C). The best water- H_2O_2 selectivity of ~12 was observed in a CMS-3 membrane at an H_2O_2 concentration of 43 mass-% with a total flux of $6.15 \times 10^{-3} \text{ g h}^{-1} \text{ cm}^{-2}$. For CMS-7, values of 9.2 and $9.6 \times 10^{-3} \text{ g h}^{-1} \text{ cm}^{-2}$ were found for water- H_2O_2 selectivity and total flux, respectively, at the same H_2O_2 concentration. The total permeated flux increased with temperature at the cost of selectivity for both membranes. Extended-term immersion of CMS-3 and CMS-7 membranes in 35 mass-% H_2O_2 indicated that both were quite stable for tests carried out over periods of 162 and 145 days, respectively.

2.7 Methods for Purifying Hydrogen Peroxide

Methods for concentrating hydrogen peroxide may not necessarily improve its purity; quite often the opposite is achieved if non-volatile contaminants accumulate in the concentrated product after the water is driven off. Most concentrating methods require a more than one-step operation to arrive at a product with both the desired purity and the required H_2O_2 concentration.

2.7.1 Purification of Hydrogen Peroxide by Distillation

The Shell Development Co. of Emeryville, CA, used a continuously operating flash distillation unit operating at low pressure and temperatures below 333 K (60 °C) to prepare some 5-gal storage samples of HTP purified by additional distillation [165, 166]. Samples of HTP-98 prepared by distillation at low pressure and temperature were prepared for long-term ground storage tests.

Highly purified hydrogen peroxide can be obtained by vacuum distillation from the products of a peroxysulfate process when the underflow of a fractionation column is condensed [167].

High-purity hydrogen peroxide can be obtained by fractionated sublimation from a frozen mixture of hydrogen peroxide, water and dihydrate in a thin film in ultrahigh vacuum, leaving the less volatile H_2O_2 behind [168]. The use of a microbalance enabled the investigators to quantify the stepwise distillation process. Infrared spectra were taken periodically during the sublimation to monitor progress of the purification process.

2.7.2 Purification of Hydrogen Peroxide by Recrystallization

Concentrating and purifying hydrogen peroxide by freezing and crystallization is a much safer process than heating and distillation.

In one crystallization concentrating process, the 90% H_2O_2 to be purified is charged to a stirred crystallizer with a conical bottom on top of a long cooling-jacketed rectifying column in which liquid enters at the bottom, and the crystals slowly sink in the opposite direction [169]. Because the density of the crystals is higher than that of the mother liquor, they settle to the bottom of the crystallizer, but are kept in suspension by the upward flow of additional liquid to be frozen and concentrated. This process can be carried out as a batch process or a continuous process, but it would be very difficult to scale it up because in a wider column back mixing would occur. In the continuous process, crystals sink to the bottom, melt, and then become the washing fluid for the younger crystals in the upper layers. The H_2O_2 starting material is cooled in a rectifying column to such an extent that there forms a two-phase system consisting of a solid crystal phase and a liquid mother liquor. The temperature along the rectifying column is so controlled that it increases slowly from one end to the other. Owing to the higher density of the crystallized hydrogen

peroxide, the crystals and the mother liquor flow in a countercurrent relative to one another. A disadvantage of that continuous suspension crystallization process is the sophisticated equipment required to carry it out. Such a technical outlay appears justified only if very highly concentrated hydrogen peroxide is required regularly and/or in large amounts. If one wants to scale up this process, as the diameter of the rectifying column increases, unforeseeable back-mixing occurs, as a result of which both the purification function is impaired, and the process efficiency is decreased considerably. The rectifying column according to this patent is in principle operated as a gravity washing column. In the lowermost portion of the column, some of the crystals melt again, and the melt thus acts as the washing medium. In such washing columns, working on the countercurrent principle, solid-liquid separation and further purification of the solid take place in one apparatus, but the scale-up problems remain.

In another version of a crystallization process, a batch process suitable for producing small quantities of the pure product, seed crystals of pure frozen hydrogen peroxide are first coated on a cold panel prior to introducing the charge to be concentrated and purified [170]. The use of seed crystals avoids the notorious tendency of hydrogen peroxide solution to supercool. After the cold panel is covered with frozen H_2O_2 , the mother liquor is drained, and the crystals are melted. The process can be repeated if needed and will yield HTP with >90% H_2O_2 .

A crystallization process for the continuous preparation of highly concentrated hydrogen peroxide starting out with >80 mass-% H_2O_2 operates by suspension crystallization and aftertreatment of the H_2O_2 crystals [171]. The aftertreatment by countercurrent washing in a hydraulic washing column with freshly molten hydrogen peroxide as the washing medium in a packed crystal bed results in crystals with 99.9 to 100 mass-% H_2O_2 and a TOC, nitrate, phosphate, nickel, and tin content of less than 4 mg/L.

2.7.3 Purification of Hydrogen Peroxide by Adsorption

Organic contaminants in hydrogen peroxide can be removed by adsorption on activated carbon (activated charcoal) to make ultrahigh purity hydrogen peroxide [172]. Other methods for reducing the amount of dissolved organic compounds include treatment of the crude product with polyethylene, ion exchange, or extraction with immiscible hydrocarbons.

Hydrogen peroxide (15–80% H_2O_2) can be purified and stabilized by passing it through an absorption column packed with granular activated non-alkaline alumina [173].

2.7.4 Purification of Hydrogen Peroxide by Ion Exchange

There have been several instances where HTP was found to be slowly decomposing in the storage yard behind the rocket test stand, and as a matter of precaution, the

entire batch of HTP had to be destroyed. It would be nice if there was a filter apparatus no bigger than a 55-gallon drum where the contaminated HTP could be poured through, which would remove all contaminants and give the HTP a new lease on life. Ion-exchange resins might be one of the methods for purification. Most ion exchange resins have been applied to hydrogen peroxide purification at the production site. There is no experience with a field unit that would achieve the same objective with aged HTP. Acid-treated β -stannic acid granules have been used as an ion-exchange bed for removal of transition metal cations from HTP [166, 174, 175]. Various combinations of inorganic ion exchange media including tin(IV) phosphate were evaluated but turned out not to be more effective than β -stannic acid alone in reducing the decomposition rate of the treated HTP. Evaluation of HTP-90 that had been treated by a β -stannic acid bed and stored in aluminum for approximately 1 year showed the HTP to have about 1/3 of the decomposition rate of the untreated feedstock.

In one patented purification process, the hydrogen peroxide solution is passed through a membrane with a very small pore size, which contains a hydrogen-loaded ion-exchange resin that is capable of removing alkali and alkaline earth metal ions from the solution [176].

While it is relatively easy to remove cation contaminants by cation-exchange resins, the removal of anion contaminants by ion exchange has been more difficult [177]. Resins of the type Amberlite IRA-400 have worked well. Acid impurities can be removed by passing hydrogen peroxide through an anion exchange resin bed loaded with bicarbonate anion [178]. Ion exchange resins of the type Amberlite IRA-400, Amberlite IRA-401, Dowex-1 or Dowex-2 can be used for that purpose. Passing HTP through a tightly packed column of ion exchange resins as is commonly done with aqueous solutions has resulted in occasional explosions. It is safer to pass the HTP through a fluidized bed of ion-exchange resin particles where concentrated local heat evolution is avoided, and heat is carried away with the exiting liquid [179].

Hydrogen peroxide in the concentration range 5–70% can be purified by ion exchange with a strongly basic anion-exchange resin, followed by treatment with a cation-exchange resin [180].

2.7.5 Purification of Hydrogen Peroxide by Reverse Osmosis

One method to purify hydrogen peroxide regardless of its concentration is by reverse osmosis. Hydrogen peroxide that is commonly used in the wafer cleaning and surface conditioning processes in the semiconductor industry must have exceptional purity. The operation of a multi-stage reverse osmosis purification plant has been modeled mathematically as a non-linear programming problem [181]. The network model integrated reverse osmosis membrane modules, mixers, and split functions, defined by the equations of mass balances, and a transport model for the description of the permeate flux and the metal rejection coefficients at each membrane stage.

A reverse osmosis process for manufacturing highly pure aqueous hydrogen peroxide used aromatic polyamide, polypiperazineamide, polysulfone, or polyacrylonitrile membranes [182].

3 Physical Properties of Hydrogen Peroxide

Hydrogen peroxide is an energetic compound, and its physical properties must be known accurately to safely design rocket engines and other machines that use the energy provided in the hydrogen peroxide molecule and its decomposition. Studies of the molecular structure through spectroscopic methods allow us to calculate the thermodynamic properties, which in turn are needed to calculate the theoretical performance as a rocket propellant. The determination of the physical properties of hydrogen peroxide is difficult. For one, it is difficult to obtain highly pure H_2O_2 where residual water and other contaminants do not give wrong measurements. For another, even if pure H_2O_2 can be obtained, sometimes pure H_2O_2 is decomposing already while its physical properties, in particular those at elevated temperatures, are being measured. The molecular mass of hydrogen peroxide is 34.0147 g/mol.

Many physical properties were determined not only for H_2O_2 with its natural occurrence of deuterium and ^{18}O , but also for hydrogen peroxide where varying amounts of H atoms had been replaced by deuterium atoms (D, ^2H) or varying amounts of ^{16}O were replaced by ^{18}O . Such isotopomer compounds are used for tracer studies in kinetic rate determinations, in environmental studies, or in the determination of physical properties. This isotope substitution brings about measurable changes in physical properties. Most often, isotope substitution is used to identify absorption bands in infrared and Raman spectra, since the isotope shift is quite pronounced. There is no application of deuterated hydrogen peroxide in rocket propulsion, and we do not summarize the literature on HOOD and DOOD. However, tons and tons of heavy water are circulating in heavy-water moderated nuclear power plants, and D_2O in close proximity to nuclear radiation forms noticeable quantities of D_2O_2 . Thus, there is quite a bit of interest in D_2O_2 and its properties in comparison to H_2O_2 .

Hydrogen peroxide was evaluated as an oxidizer for an advanced liquid propellant staged combustion feasibility program, and its physical, chemical, and handling properties were compiled in a handy summary report, although most of the data were taken from the book by Schumb and from HTP manufacturers' product bulletins [183]. It is just that these product bulletins are no longer available because some of HTP manufacturers are no longer in business. However, the Anderson summary is still available on the Internet, although the quality of reproduction is poor, and some of the text is hard to read. The Anderson [183] summary is the most comprehensive collection of hydrogen peroxide data that we have found so far on the Internet.

3.1 Freezing Point of Hydrogen Peroxide

The high freezing point of hydrogen peroxide is one of the disadvantages for its use as a rocket propellant. Consequently, various freezing point depressants have been evaluated to widen the liquid range of hydrogen peroxide.

It is very difficult to determine the freezing point of hydrogen peroxide and its aqueous solutions because it has a notorious tendency to supercool (Table 2).

Table 2: Freezing point of hydrogen peroxide.

Composition Mass-% H ₂ O ₂	Freezing point			Source	Year	References
	K	°C	°F			
100	272.72	−0.43	31.226	Chemical abstracts		
98	270.55	−2.60				
90	261.62	−11.53				
100	272.69	−0.461	31.170	Foley and Giguere	1951	[184]
100	272.26 ^a	−0.89	30.398	Cuthbertson, Matheson, and Maass	1928	[185]
	272.72	−0.43	31.226	Schumb, Satterfield, and Wentworth	1955	[186]

^a This is the value accepted by NIST

The purpose of some investigations was to redetermine the freezing point of pure H₂O₂, to investigate the possibility of solid solutions in the system H₂O₂-water and to use freezing point measurements for evaluating the purity of very concentrated H₂O₂ [187]. The freezing point of pure H₂O₂ was reported as −0.461°C and is believed to lie within a few thousandths of a degree of the true value because it is the highest temperature observed in a direct determination and could be duplicated to the limit of accuracy of the measurements (0.001°) with two different samples. The melting point of the dihydrate was 221.05 K = −52.10°C. Two eutectics occur at concentrations of 45.2 and 61.2% H₂O₂ and at temperatures of 220.7 and 216.6 K (−52.4 and −56.5°C), respectively. Using a radioactive tracer technique it was determined that water and H₂O₂ do not form solid solutions together.

If hydrogen peroxide is used as a solvent, and the freezing point depression used as a measure of the molecular mass of the dissolved species, the cryoscopic constant is 1.72 [184, 187].

The triple point was estimated to be 272.73 K = −0.42°C at 34.5 Pa = 0.26 mm Hg [188].

3.1.1 The Hydrogen Peroxide/Water Liquid/Solid Phase Diagram

Hydrogen peroxide and water form two eutectics and a peritectic, indicating formation of some type of hydrate in the solid state. The eutectic points are at 45.2 mass-% H_2O_2 with a melting point of $220.95\text{ K} = -52.2^\circ\text{C}$ and at 61.2 mass-% H_2O_2 with a melting point of $217.05\text{ K} = -56.1^\circ\text{C}$. Compound formation, a dihydrate, $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$ appears to occur at 48.6 mass-% with a melting point of $221\text{ K} = -52^\circ\text{C}$.

The original phase diagram (Figure 2) in Schumb is cluttered with numerous data points of dubious origin. The wide scatter of data points is due to the tendency of these mixtures to supercool.

Figure 2: Solid-liquid phase diagram of the hydrogen peroxide-water system. (Reproduced and modified from [4].)

A similar phase diagram was shown in a Laporte Chem brochure and that was the one that was used in a 1968 edition of a book on rocket propellants; it is shown in Figure 3.

A thorough understanding of the phase diagram of the H_2O_2 - H_2O system is required for all efforts to concentrate and purify H_2O_2 by fractionated crystallization or zone melting. Initial attempts to separate H_2O and H_2O_2 by fractionated crystallization did not provide clear results. An attempt was made to determine the exact composition of the first crystals that separate out on freezing solutions of H_2O_2 and H_2O of various concentrations. Special care was taken to ensure complete removal of any liquid wetting the solid phase. In all cases, the crystals were found to contain both components and in proportions usually different from those in the mother liquor [189]. The results from this test were inconclusive.

Figure 3: Liquid phase diagram of the $\text{H}_2\text{O}_2\text{-H}_2\text{O}$ system. (Reproduced and modified from Laporte Chem. Ltd.)

Hydrogen peroxide forms hydrates with specific stoichiometric ratios. Crystalline $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$ and its deuterated analog were studied at 80 K by IR and Raman spectroscopy [190]. The six O—H stretching modes predicted by group theory were observed and correlated with the three kinds of H-bonds found by X-ray diffraction. The introduction of one peroxide bond per three mols of H_2O in the crystal lattice of ice lowers the symmetry and reduces the stability of the hydrate considerably, although the intermolecular forces should be almost the same in ice and $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$.

The discovery of H_2O_2 in the ice on the surface of the moon Europa [52] in orbit around the planet Jupiter has revived interest in the $\text{H}_2\text{O}/\text{H}_2\text{O}_2$ phase diagram. Early XRD measurements had shown that an intermediate compound phase exists in crystalline mixtures, the dihydrate $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$ [191]. This compound was also identified in the determination of the equilibrium phase diagram of water/hydrogen peroxide [187], indicating that when solutions approach equilibrium, there is competition between the formation of three phases: water ice, H_2O_2 ice, and the dihydrate. This dihydrate phase was subsequently identified using infrared spectroscopy [192]. The temperatures at which the dihydrate formed in those experiments (140–200 K) were like those on the warmer icy satellites of Jupiter; see also [193, 194].

3.1.2 Supercooling of Hydrogen Peroxide

The complete mapping of the freezing point in the H_2O_2 - H_2O system is complicated by the fact that hydrogen peroxide (like water or hydrazine) has a tendency to supercool when the temperature is lowered gradually, and no nucleation sites are provided. H_2O_2 solutions with any H_2O_2 concentration are capable of supercooling, but the phenomenon is most frequently observed with solutions above 50% H_2O_2 where supercooling of 10 to 50 °C below the generally accepted freezing point is not uncommon [195, 196].

The deuterium isotopomer of H_2O_2 , D_2O_2 , is even more prone to supercooling and assumes a highly viscous, glassy state at temperatures as low as 194 K = -79 °C (dry ice) or even 88 K = -185 °C (LN_2).

A water solution containing 45.5 to 87 mass-% H_2O_2 was found to form a glass when immersed in liquid oxygen at 90 K [197]. The boundary between crystallization and glass formation at 45.5 mass-% is very sharp and corresponds to the eutectic point of H_2O and H_2O_2 , while the boundary at 87 mass-% is less marked with a leeway of ~5 mass-% and coincides with the change in the slope of the melting point versus concentration curve for quickly frozen solutions. A D_2O solution containing 80 mass-% D_2O_2 was also found to form a glass in liquid oxygen, with no evidence of subsequent crystallization.

3.1.3 Freezing Point Diagrams of Binary Hydrogen Peroxide Mixtures

3.1.3.1 Freezing Point Diagrams of Solutions of Solids in Hydrogen Peroxide

Hydrogen peroxide is a good solvent, as good as water, and will form solutions with many inorganic salts. The objective of dissolving oxidizing salts in H_2O_2 is to lower the freezing point, increase the density, and improve its performance as a rocket propellant. One must be careful not to dissolve any combustible salts or organic compounds in HTP, or the mixtures may become detonable.

Solutions of inorganic oxidizing salts in H_2O_2 have been proposed as liquid propellant oxidizers. The addition of salts lowers the freezing points and the vapor pressure of H_2O_2 . Some of these solutions of ammonium salts in H_2O_2 can also be used as monopropellants. Freezing point diagrams of several binary and ternary systems involving H_2O_2 (PERSOL, OXSOL, PERHAN) will also be described in *Encyclopedia of Oxidizers*, chapters "Nitrate Oxidizers" and "Hydroxylammonium Salts". A powerful and low-freezing oxidizer called PERSOL-1 can be obtained by dissolving ammonium nitrate (AN) in hydrogen peroxide/water mixtures [198, 199]. The freezing point diagram of the ternary system AN/ H_2O_2 / H_2O is shown in Figure 4.

One preferred composition of PERSOL-1 contains 55.6% AN, 22.2% H_2O_2 , and 22.2% H_2O . This blend freezes at 276 K (3 °C) and has a density of 1.361 g/cm³. It can serve as an oxidizer for bipropellant or hybrid rocket propellant combinations. Monopropellants can be formulated by emulsifying this oxidizer with hydrocarbons

Figure 4: Freezing point isotherms diagram of ternary $\text{H}_2\text{O}_2/\text{H}_2\text{O}/\text{AN}$ oxidizer solutions also called PERSOL-1. (Reproduced and modified from [199].)

or by dissolving amine nitrate salts such as alkylammonium nitrate or alkanolammonium nitrates having one, two or three carbon atoms. Instead of AN, hydrazinium nitrate (HN) can be dissolved in H_2O_2 to form a mixture called “PERSOL-2” [200]. The freezing point diagram of the $\text{HN}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ system is illustrated in Figure 5. One

Figure 5: Freezing point diagram of $\text{HN}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ system. (Reproduced and modified from [200].)

would hesitate to mix hydrazine compounds and hydrogen peroxide. It is known that hydrogen peroxide and free hydrazine or hydrazine hydrate react instantly in a hypergolic manner, but the hydrazine molecule appears to be stabilized against such an attack by protonizing it and forming the hydrazinium(1+) ion. When looking at PERSOL-2 type oxidizers, there is still some concern that the strong oxidizer H_2O_2 might attack the fuel cation N_2H_5^+ , leading to hydrogen azide as an unwanted byproduct of reaction.

A very elegant, alternate way to represent freezing point data such as those in the triangular chart above is to display them as a 3-D color-coded graph (Figure 6) [201].

Figure 6: Freezing point diagram of $\text{HN}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ system. (From [201].)

Many salts form hydrates containing water of crystallization. Similar “hydrates” are formed with hydrogen peroxide instead of water in the sphere of hydration, except they are called *peroxidates*. Covalently bonded chemical adducts are formed from hydrogen peroxide and inorganic nitrates such as AN, sodium nitrate, potassium nitrate, ammonium dinitramide, or combinations thereof. These chemical adducts are referred to as *peroxidates* or persalts. They may be used as oxidizers in propellants, explosives, and pyrotechnics [202]. They represent hydrogen peroxide in solid form at room temperature, similar to crystalline hydrates. These adducts can also be used to produce low water content liquid hydrogen peroxide in a distillation tower. For instance, AN has a higher affinity to hydrogen peroxide than to water. The preferred H_2O_2 :AN molar ratio is 1:1, but discrete adducts with lower and higher H_2O_2 contents may also be formed. DSC thermograms indicated the formation of several different poly-peroxidates. On heating of the 1:1 adduct, four endotherms occurred at 327.09, 363.88, 403.97, and 434.26 K (53.94, 90.73, 130.82, and 161.11 °C). The 1:1 adduct is a solid at room temperature and starts to decompose at 423 K (150 °C). In a heated $\text{AN}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixture the water will distill off first, leaving the solid peroxidate behind. The solid can then be slowly decomposed under vacuum to release anhydrous hydrogen peroxide vapors that sublime and can be condensed in a cold trap. Similar, but less strongly hydrated salts can be obtained from hydrogen peroxide and sodium nitrate or potassium nitrate.

The freezing points (also called crystallization points) of AN solutions in 3% H_2O_2 (top curve) and 35% H_2O_2 (bottom curve) are shown in Figure 7. (It would be much more useful to have the AN diagram for 90% or 70% HTP instead of 3 and 35%.)

Figure 7: Freezing point of H_2O_2 /AN mixtures. (Chart created by Schmidt 2020, based on data from [202].)

A low-freezing oxidizer mixture containing 55% H_2O_2 , 39% ammonium nitrate, and 6% water was thoroughly characterized in drop weight impact sensitivity, cap sensitivity, boosted detonability, card gap sensitivity, and adiabatic compression sensitivity tests at room temperature and even at elevated temperature [203]. It was concluded that addition of AN to HTP does not worsen its sensitivity to mechanical and hydrodynamic shock and to adiabatic compression.

The density, viscosity, and freezing point diagram of ammonium nitrate solutions in HTP were measured. Ammonium nitrate in H_2O_2 forms a eutectic containing 46% AN [204].

In an effort to reduce the melting or glass transition temperature and to increase stability and to prevent aging without ruining the oxygen balance, ammonium nitrate or ammonium dinitramide was dissolved in hydrogen peroxide with purities from 60 to 80% [205, 206]. Such oxidizer solutions enable low operation temperatures far below 233 K (-40°C). They were tested as hypergolic propellants in combination with an energetic ionic liquid (EIL) based on AMIM DCA as fuel including appropriate cata-

lysts enhancing hydrogen peroxide decomposition. Hypergolic lab-scale ignition tests resulted in very short ignition delay times comparable to hypergolic combinations currently in operation.

The solubilities of perchlorate salts of alkali metals and alkaline earth metals at 273 K (0 °C) in anhydrous hydrogen peroxide are: LiClO_4 62.3, NaClO_4 42.12, KClO_4 3.52, RbClO_4 4.73, CsClO_4 15.34, $\text{Mg}(\text{ClO}_4)_2$ 70.1, $\text{Ca}(\text{ClO}_4)_2$ 97.7, and $\text{Sr}(\text{ClO}_4)_2$ 113.3 mass-% [207]. The solvates $\text{Ca}(\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}_2$ and $\text{Sr}(\text{ClO}_4)_2 \cdot \text{H}_2\text{O}_2$ were obtained as crystalline solids. LiClO_4 and $\text{Mg}(\text{ClO}_4)_2$ solvates could not be characterized due to their instability. The other perchlorates did not form solvates.

The $\text{Mg}(\text{ClO}_4)_2/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ system was studied at 293 K (20 °C) to determine the optimum conditions for the preparation of anhydrous H_2O_2 by using anhydrous $\text{Mg}(\text{ClO}_4)_2$ (known as a very effective adsorbent for water vapor) as a desiccant [208]. Equilibrium solid phases are $\text{Mg}(\text{ClO}_4)_2 \cdot n\text{H}_2\text{O}_2$ ($n=2, 4, 6$). The pure H_2O_2 can be obtained by vacuum heating of $\text{Mg}(\text{ClO}_4)_2 \cdot n\text{H}_2\text{O}_2$ solutions at 293 K (20 °C). At $\text{Mg}(\text{ClO}_4)_2$, H_2O ratios corresponding to hexa- or tetrahydrates, 80–97% H_2O_2 was obtained, and anhydrous H_2O_2 was obtained for ratios corresponding to the dihydrate. The H_2O_2 yield was 94–97%.

3.1.3.2 Freezing Point Diagrams of Liquid/Liquid Mixtures with Hydrogen Peroxide

Hydrogen peroxide is readily miscible with inorganic and many organic liquids. The reason for adding other liquids to HTP would be to lower its freezing point, increase the specific impulse as a monopropellant, or improve the hypergolic ignition characteristics with organic fuels. If these added liquids are combustible fuels, the mixtures may be detonable. Other liquid additives that change the pH of H_2O_2 may destabilize it simply due to the change in pH. The destabilizing effect of KOH (a solid, not a liquid) on H_2O_2 was investigated after a tank with such a solution intended to be used in a chemical laser exploded during storage. Therefore, such mixtures should not be prepared in large quantities unless they are thoroughly characterized. There is an account of a not very well documented accident in WWII Germany where a mixture of HTP and ethanol (or methanol?) was transported and exploded. Despite this catastrophe, H_2O_2 /ethanol mixtures continue to be evaluated as rocket propellants. Shortly after 1935, a very serious accident occurred in Germany where physicists working for German Army Command tried to develop a more energetic H_2O_2 monofuel, but the propellant exploded and killed three people [209].

In the hydrogen peroxide/nitric acid binary system, the addition of HNO_3 to H_2O_2 would lower its freezing point of H_2O_2 and make the oxidizer hypergolic with many fuels with which H_2O_2 by itself might not otherwise react. Electrical conductivity measurements indicate a minimum at the formation of a peracid which is not capable of ionizing.

The freezing point of $\text{H}_2\text{O}_2/\text{CH}_3\text{OH}$ mixtures is shown in Figure 8 in comparison to those of $\text{H}_2\text{O}/\text{CH}_3\text{OH}$ mixtures. A difficulty was encountered with methyl alcohol beyond 51.5% H_2O_2 because the liquid froze to a glass [210].

Figure 8: Freezing point of hydrogen peroxide/methanol mixtures in comparison to water/methanol mixtures. (Reprinted and modified from [210], with permission from © 1929 American Chemical Society; permission conveyed through RightsLink.)

The freezing point diagrams of mixtures of hydrogen peroxide with many organic polar solvents have been investigated.

Instead of using the more volatile methanol or ethanol as freezing point depressants in formulating a monopropellant more energetic than plain HTP, alcohols and diols with low vapor pressure have been tested as freezing point depressing fuels for HTP. One such mixture contained 67.8% H_2O_2 , 6.6% diethylene glycol, and 25.6% water, and it was thoroughly characterized in drop weight impact sensitivity, cap sensitivity, boosted detonability, card gap sensitivity, and adiabatic compression sensitivity tests at room temperature and even at elevated temperature [211].

3.1.4 Hydrogen Peroxide Phase Transitions under Very High Pressure

The pressure-induced phase transition and chemical decomposition of hydrogen peroxide and its mixtures with water at pressures up to 50 GPa were studied using confocal micro-Raman spectrometry and synchrotron X-ray diffractions [212]. The X-ray results indicated that pure H_2O_2 crystallizes into a tetragonal structure ($P4_12_12$), the same structure previously found in pure H_2O_2 at low temperatures. The tetragonal phase (H_2O_2 -I) is stable to 15 GPa, above which it transforms into an orthorhombic structure (H_2O_2 -II) over a relatively large pressure range between 13 and 18 GPa. The phase I $\rightarrow$ II transition pressure decreased in diluted H_2O_2 to around 7 GPa for the 41.7% H_2O_2 and 3 GPa for the 9.5% H_2O_2 , based on measurements of the splitting of the $\nu_s(\text{O}-\text{O})$ stretching mode. Above 18 GPa, H_2O_2 -II gradually decomposed to a mixture of H_2O and O_2 , with complete decomposition at around 40 GPa for pure and 45 GPa

for the 9.5% H_2O_2 . Upon pressure unloading, H_2O_2 also decomposed to H_2O and O_2 mixtures, occurring at 2.5 GPa for pure and 1.5 GPa for the 9.5% mixture. At H_2O_2 concentrations below 20%, decomposed mixtures formed oxygen hydrate clathrates at around 0.8 GPa (just after H_2O melts). The compression data of pure H_2O_2 and the stability data of the mixtures indicated that the high-pressure decomposition is likely due to the pressure-induced densification, whereas the low-pressure decomposition may be related to the heterogeneous nucleation process associated with H_2O_2 melting.

3.2 Boiling Point of Hydrogen Peroxide

The boiling point of aqueous hydrogen peroxide solutions depends on the hydrogen peroxide concentration (Table 3). If hydrogen peroxide solutions are concentrated by boiling away the water, the boiling point of the remaining solution will gradually increase. The boiling point of 100% H_2O_2 is 425 K (152°C), substantially higher than that of water.

Table 3: Atmospheric pressure boiling points of hydrogen peroxide solutions.

Hydrogen peroxide concentration		Temperature

3.2.1 Sublimation of Solid Hydrogen Peroxide

Sublimation of H_2O from $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ ice mixtures may be one mechanism explaining how H_2O_2 becomes enriched in the ice crust of planetary bodies. The growth of thin films of crystalline H_2O_2 and $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$ (dihydrate) in ultrahigh vacuum by distilling an aqueous solution of hydrogen peroxide was investigated using IR reflectance spectroscopy and UV-visible reflectance [213]. The three different crystalline phases: water,

dihydrate, and hydrogen peroxide, have very different sublimation rates, making sublimation a viable method to isolate the less volatile component, crystalline H_2O_2 . Using infrared (IR) spectroscopy and thermogravimetric analysis (TGA), the isothermal decomposition of the metastable $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$ was examined at 151.6 K. This decomposition occurs by fractional distillation through the preferential sublimation of water, which leads to the formation of pure hydrogen peroxide [214].

3.3 Critical Constants of Hydrogen Peroxide

The critical point conditions for hydrogen peroxide can only be predicted by vapor pressure and density calculations and are not accessible to experimental verification due to incipient decomposition (Table 4).

Table 4: Critical point property data of hydrogen peroxide.

Critical temperature, T_c		Critical pressure, p_c			Source	Year	References
K	°C	MPa	atm	bar			
730	457	21.614	214		Scatchard, Kavanagh, and Ticknor	1952	[215]
728	455			220	Nikitin et al.	1995	[216]

The critical temperatures and the critical pressures of aqueous solutions with mass fractions of hydrogen peroxide from 0 to 0.9 were measured using a pulse-heating method applicable to thermally unstable substances [216]. The critical temperature and the critical pressure of pure hydrogen peroxide were then determined by extrapolation. The uncertainty assigned by NIST Thermodynamics Research Center to the Nikitin critical point data was ± 15 K and ± 20 bar [217].

3.4 Density and Compressibility of Hydrogen Peroxide

3.4.1 Density of Hydrogen Peroxide and Hydrogen Peroxide Solutions

The density of pure hydrogen peroxide as a function of temperature and the density of aqueous H_2O_2 solutions as a function of H_2O_2 concentration and temperature are summarized in this section. Some of the tables overlap in their coverage, and the data have not yet been consolidated. Measurement of the density is one of the simplest methods to obtain approximate numbers for the hydrogen peroxide concentrations. A commonly accepted number for the density of 100% H_2O_2 at 298 K is 1.4425 g/cm^3 .

The sample of pure H_2O_2 used for the density determination listed in Table 5 was purified and concentrated by distillation to 30%, evaporation to 90%, and then by fractionated crystallization to 100% H_2O_2 [218].

Table 5: Density of pure hydrogen peroxide.

Data source: [218].

Table 6 is a compilation of density data for hydrogen peroxide solutions, gathered from different literature sources. One of the better density determinations for 0–100% H_2O_2 at 273 K was performed by [219, 220] as shown in Table 7. Another more recent set of data for a wider temperature range agrees quite well with the 273 K data above. Only the 273 K data are shown in Table 8. From these data the density at five different temperatures can be calculated as a function of the H_2O_2 concentration by using the following polynomial equation

$$\rho = a + bw + cw^2 + dw^3$$

where ρ is the density in g/cm^3 , and w is the weight fraction of H_2O_2 , and a , b , c , and d are the temperature-dependent coefficients listed in Table 9.

Another equation based on curve-fitted data from six different sources expresses the density as a function of both concentration and temperature from 273 to 466 K (from 0 to 193 °C = 32 to 379 °F) over a concentration range of 60 to 100 mass-% H₂O₂ [7]:

$$\rho = 1.0479 + 2.455 \times 10^{-3} W + 1.781 \times 10^{-5} W^2 - 6.76 \times 10^{-4} t - 2.4 \times 10^{-7} t^2 - 3.98 \times 10^{-6} Wt$$

where ρ is the density in g/cm³, W is the mass-% H₂O₂, and t is the temperature in °C. Figure 9 gives the density of H₂O₂ solutions as a function of H₂O₂ concentration and temperature.

The densities of binary solutions of H₂O₂ and H₂O from 273 K (0 °C) down to their respective freezing points were measured by a dilatometric method [222]. An extrapolation of the density plot gave a value of 1.4730 g/mL for the density of pure liquid H₂O₂ at 273 K (0 °C). When measuring the volume changes during solidification, it was found that solutions containing less than 45 mass-% H₂O₂ expanded on freezing, and that this effect was decreasing with increasing concentration. The reverse was true of

Figure 9: Density of aqueous H₂O₂ solutions. (Redrawn based on Laporte Chem. data.)

solutions containing over 65% H₂O₂. Observations on supercooling indicated that no solid solutions were formed between the two components.

In this book, we have collected mostly the density data for H₂O₂ solutions of practical interest containing more than 50% H₂O₂. If one plots the density as a function of H₂O₂ concentration over the entire range of compositions, one will notice that there are two areas where the linearity of the curve changes a little, one between 20 and 30% H₂O₂ and one between 70 and 80% H₂O₂ (Figure 10). This slight undulation is not evident in other published density data, which assume a simpler shape (Figure 11). This deviation from a straight line relationship is possibly caused by cluster formation at certain stoichiometries.

Figure 11 shows the density of hydrogen peroxide/water mixtures as a function of hydrogen peroxide content at 273 and 291 K (0 and 18 °C), but the function was drawn as an almost straight, slightly concave line [194].

Volumetric and calorimetric data were used to calculate the excess functions for mixtures of water and hydrogen peroxide over the entire concentration range, also in comparison with those for the corresponding deuterium isotopomer compounds [223]. A maximum in the excess-volume curves, presumably related to the formation of the compound H₂O₂•2H₂O, persists in the liquid mixtures over an appreciable temperature range above the melting point of H₂O₂. New density determinations were carried out on mixtures of heavy water and deuterium peroxide at 273 and 293 K (0 and 20 °C), and the effect of deuterium peroxide on the temperature of maximum density of heavy

Figure 10: Density of hydrogen peroxide-water mixtures. (Republished and modified from [9], with permission of © 1999 Royal Society of Chemistry; permission conveyed through Copyright Clearance Center Inc.)

water was measured and compared with that of deuterated alcohols. It was concluded that the structure of liquid water is easily penetrated by hydrogen peroxide molecules.

It is well known that water is one of the few liquids that expand on freezing. The question is now: “How will mixtures of water and hydrogen peroxide behave on freezing?” This is an important question because containers in which solutions with lower concentrations of hydrogen peroxide are transported and stored may rupture if allowed to freeze accidentally in cold climates.

A set of curves for the density of HTP at concentrations between 84 and 89 mass-% and temperatures between 273 and 303 K (0 and +30 °C) was constructed to aid in the analysis of H₂O₂/H₂O mixtures [224].

The density of H₂O₂/H₂O mixtures at 295.7 K (22.6 ± 1.2 °C) can be expressed by the equation [225]:

$$\rho_0 = A + Bx + Cx^2$$

Figure 11: Density of hydrogen peroxide-water mixtures at 273 and 291 K. (Reproduced and modified from [194], with permission from © 1950 Wiley VCH GmbH.)

where ρ_0 is the density in g/cm³, x is the mass-% H₂O₂, and A, B, and C are constants: $A = 0.9991 \pm 0.0001$, $B = (3.369 \pm 0.003) \times 10^{-3}$, and $C = (1.058 \pm 0.003) \times 10^{-5}$.

The density of H₂O₂/H₂O solutions has been determined experimentally for temperatures in the range 273–269 K (0–96 °C), but the great difficulties in measuring densities at higher temperatures with incipient gas evolution makes it necessary to use calculation methods and extrapolate [226].

3.4.2 Coefficient of Thermal Expansion of Hydrogen Peroxide

The coefficients of thermal expansion taken from some old manufacturers' literature and listed in Table 10 do not match the average coefficients of thermal expansion calculated from curve-fitted data of measured densities taken from six different sources and illustrated in Figure 12.

Table 10: Coefficient of thermal expansion of hydrogen peroxide.

Concentration	Coefficient of thermal expansion $\times 10^4, ^\circ\text{C}^{-1}$				
Mass-% H_2O_2	Temperature range, $^\circ\text{C}$				
	0–20	20–40	40–60	60–80	80–100
60	6.8	7.2	7.5	8.0	8.8
70	7.1	7.4	7.7	8.2	9.0
80	7.4	7.5	7.8	8.3	9.4
90	7.7	7.6	7.9	8.5	9.9
100	8.1	7.7	7.9	8.8	10.6

Data source: Laporte Chem. Co.

Figure 12: Coefficient of thermal expansion of hydrogen peroxide. (Reproduced and modified from [7].)

3.4.3 Compressibility of Hydrogen Peroxide

Adiabatic compressibility data are usually derived from velocity of sound measurements in liquids. The adiabatic compressibility of H_2O_2 solutions was calculated from experimental density and sonic velocity data covering a temperature range of 276.6 to 306.6 K (3.5 to 33.5 $^\circ\text{C}$ = 38.3 to 92.3 $^\circ\text{F}$) and a concentration range of 0 to 93.4 mol-%

(0 to 96.5 mass-%) [227]. These data were used to plot the adiabatic compressibilities of propellant-grade H_2O_2 solutions shown in Figure 13. Although no experimental data have been reported on the isothermal compressibility of H_2O_2 , the adiabatic compressibility, density, and heat capacity data were used to calculate an isothermal compressibility of $26.514 \times 10^{-12} \text{ cm}^2/\text{dyn}$ ($26.865 \times 10^{-6} \text{ atm}^{-1}$) for 100% H_2O_2 at 293 K ($20^\circ\text{C} = 68^\circ\text{F}$).

Figure 13: Adiabatic compressibility of hydrogen peroxide. (Reproduced and modified from [7].)

3.4.4 Velocity of Sound in Hydrogen Peroxide

The sonic velocity was measured for a temperature range from 276.6 to 306.6 K (3.5 to $33.5^\circ\text{C} = 38.3$ to 92.3°F) and a concentration range of 0 to 93.4 mol-% H_2O_2 (0 to 96.5 mass-%) [227, 228]. The unusually low compressibility of hydrogen peroxide was

explained by assuming a three-dimensional network of molecules held together by hydrogen bonding. These data were later used to plot the velocity of sound of propellant-grade H_2O_2 solutions shown in Figure 14.

Figure 14: Velocity of sound of hydrogen peroxide solutions. (Based on data from [227].)

The velocity of sound of $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures was measured over the entire range of compositions [225]. The mean and standard deviation of the temperatures at which the sound speed data were taken was $295.7 \pm 1.2\text{ K}$ ($22.6 \pm 1.2^\circ\text{C}$). To represent the sound speed data at any composition, the corrected values of sound speed were least-squares fit to the analytic (sigmoid) form

$$c_0 = \frac{(A + Dx^B)}{(1 + x^B)}$$

where c_0 is the velocity of sound in $\text{mm}/\mu\text{s}$, x is the mass-% H_2O_2 divided by C , and A , B , C , and D are fitting parameters. The resultant parameter values are $A = 1.488 \pm 0.004 \text{ mm}/\mu\text{s}$, $B = 1.636 \pm 0.183$, $C = 105.8 \pm 29.5$, and $D = 2.090 \pm 0.153 \text{ mm}/\mu\text{s}$. The experimental data and the fitted curve are shown in Figure 15; see also [229].

Figure 15: Velocity of sound in H₂O₂/H₂O mixtures at 295.7 K (22.6 °C). (Chart created by Schmidt 2020, based on data from [225].)

3.5 Vapor Pressure and Vapor Phase Composition of Hydrogen Peroxide Solutions

The determination of the vapor-pressure of pure hydrogen peroxide is important because the data makes possible the calculation of the latent heat of evaporation and Trouton's constant, the physical properties which are of particular interest when compared with the corresponding ones for water. The experimental difficulties which must be overcome in the measurement of the vapor pressure of hydrogen peroxide are that at high temperatures hydrogen peroxide decomposes when in contact with glass or mercury. A mercury manometer cannot be used directly because of the immediate decomposition that takes place when peroxide vapor comes into contact with the mercury surface, the latter being attacked and covered with scum, which makes accurate pressure readings impossible. One of the very first vapor pressure determinations for H₂O₂ gave the equation

$$\log p = - \frac{0.05223 \times 48530}{T} + 8.843$$

where p is the pressure in mm Hg, and T is the temperature in kelvin, a molecular latent heat of evaporation of 11.610 kcal/mol, and a Trouton's constant of 27.3, showing that hydrogen peroxide is associated in the liquid phase, similar to water whose Trouton's constant is 26.2 [230].

Total vapor pressure and vapor composition data for hydrogen peroxide solutions are listed in Table 11; see also Figure 16.

Table 11: Total vapor pressure and vapor composition of hydrogen peroxide solutions.

Temperature		Total vapor pressure, mm Hg				Vapor composition, mol fraction H ₂ O ₂

Data source: [215]

Curve fitting of data obtained by Scatchard, Kavanagh, and Ticknor [231] led to the following vapor pressure equation for pure H₂O₂, valid for the range from 333 to 363 K (60 to 90 °C)

$$\log p = 44.5760 - 4025.3/T - 12.996 \log T + 0.0046055T$$

where p is the pressure in mm Hg, and T is the absolute temperature in K.

The vapor pressure of hydrogen peroxide is difficult to determine experimentally, since incipient decomposition causes formation of oxygen that increases the measured pressure above the liquid sample. For this reason, vapor pressure measurements

rarely go to temperatures exceeding 340 K (70 °C). According to [232], one can derive a vapor pressure equation by curve fitting data to the Clausius-Clapeyron equation:

$$\log p_D = 24.594655 - 3375.1/T - 5.23700 \log T$$

where p_D is the vapor pressure in mm Hg, and T is the absolute temperature in K.

Charts were presented for the vapor pressure of hydrogen peroxide from 278 to 433 K (40 to 320 °F) [233]. A copy of such a chart is shown in Figure 16.

Figure 16: Total vapor pressure of aqueous hydrogen peroxide solutions. (Reproduced and modified from Laporte Chem. Co.)

Because the boiling points of water and hydrogen peroxide are so far apart ($\Delta T = 50^\circ\text{C}$), it is relatively easy to achieve H_2O_2 concentration by simple distillation. A fractionating column would certainly help achieve more effective separation and

reduce carryover of water. The vapor phase diagram of the $\text{H}_2\text{O}_2\text{-H}_2\text{O}$ system needs to be known in order to design a distillation system. Figure 17 shows the vapor phase composition diagram for two pressures: 30 mm Hg and 760 mm Hg.

Figure 17: Vapor phase composition diagram of the $\text{H}_2\text{O}_2\text{-H}_2\text{O}$ system. (Reproduced and modified from [4].)

We do not provide the numerical data on which Figure 17 is based. It may suffice to just give the boiling points of $\text{H}_2\text{O}_2\text{-H}_2\text{O}$ mixtures at atmospheric pressure as already summarized in Table 3 at the beginning of this chapter.

The total vapor pressures of binary mixtures of H_2O_2 and H_2O were measured by a static method at 303, 318, and 333 K (30, 45, and 60 °C) over the entire range of compositions [234]. The vapor-pressure composition curves exhibit a large negative deviation from Raoult's law. The activities of H_2O and H_2O_2 in their solutions were calculated based on the polarity of the two pure liquids. These data are important for the design of distillation apparatus for the concentration of H_2O_2 solutions; see also [235].

Available experimental data of the pressure dependence of temperature of non-equilibrium boiling of rapidly heated aqueous solutions of hydrogen peroxide

were used to determine the pressure(P)-temperature(T)-concentration(x) relationship [236]. A correlation was obtained for a solution under conditions of phase equilibrium (saturation surface in three-dimensional space of variables P , T , and x) in a wide range of states, including the critical state. The surface obtained was used to calculate the equilibrium composition of vapor above the equilibrated liquid as a function of x and T by solving the Duhem equation.

In continuation of this work, the dependences of total pressure and equilibrium composition of vapors on temperature and mol fraction of hydrogen peroxide in solution were calculated for a H_2O_2 - H_2O two-component two-phase system [237]. It was assumed that the relaxation to concentration equilibrium in gas at the surface of the solution would be attained quite rapidly compared to the half-life of hydrogen peroxide. Three independent approximate methods were used to calculate the total pressure, but two of these methods did not use the ideal gas approximation for the vapor phase. Approximation formulas express the dependence of pressure and composition of gas on relative concentration of hydrogen peroxide in solution and on temperature. Total pressure curves were given for the entire range of compositions at temperatures of 373, 423, 473, 523, and 573 K. Small deviations of phase diagrams from one another implied that any of three approximations may be used for the calculation of total pressure $P(x, T)$ in the $\text{H}_2\text{O}/\text{H}_2\text{O}_2$ system. Error limits of calculations were estimated. The simplest method for the calculation of total pressure was a method that was based on the closeness of the thermodynamic properties of water and hydrogen peroxide: the $P(x, T)$ function was determined by interpolation using formulas for lines of phase equilibrium of $P(T)$ of individual components.

3.6 Viscosity of Hydrogen Peroxide

3.6.1 Viscosity of Liquid Hydrogen Peroxide

Early literature described the appearance of pure hydrogen peroxide as a “syrupy consistency”. This is not supported by current data (Table 12) showing that pure H_2O_2 is not much more viscous than pure water.

Figure 18 is a graphical compilation of viscosity data for 90 and 98% hydrogen peroxide collected from four different sources and combined by Anderson [183].

3.6.2 Viscosity of Hydrogen Peroxide/Water Mixtures

The viscosity of hydrogen peroxide solutions as a function of H_2O_2 concentration is not a linear function but goes through a minimum and a maximum as illustrated in Figure 19, which shows the viscosity at three different temperatures. The S-shape of

the curve is particularly distinct at 273 K (0 °C). The shape of the curve is difficult to explain. Compound or hydrate formation as it is observed with anhydrous hydrazine and water does not occur in the H₂O/H₂O₂ liquid system. Both H₂O and H₂O₂ liquids by themselves are heavily associated due to hydrogen bonding and cluster formation.

Numerical data for viscosity data at two different temperatures are summarized in Table 13.

Similar viscosity data measured at 273 K and 291 K (0 and 18 °C) were measured already almost 100 years ago [218] and were included in Table 14. It was then that the S-shape of the viscosity curve was first noted.

3.6.3 Viscosity of Hydrogen Peroxide Vapor

The viscosity of hydrogen peroxide vapor is an important parameter in the heterogeneously catalyzed decomposition of H_2O_2 in chemical reactors. The vapor of undecomposed H_2O_2 has to diffuse toward the catalyst surface, and its flow is impeded by a flow of decomposed H_2O_2 (i.e., H_2O and O_2) in the opposite direction.

The viscosity of vapor mixtures of highly polar H_2O_2 and H_2O containing up to 65 mol-% H_2O_2 was measured by a capillary flow method at 1 atm total pressure and a temperature of 443 K (170 °C) [240]. The method of determining viscosity used was that of measurement of the pressure drop occurring upon flowing hydrogen peroxide vapor through a capillary tube at constant temperature. The viscosity of anhydrous H_2O_2 vapor at 443 K (170 °C) was found to be 144 μPs by extrapolation. Studies were

also made at 473 and 513 K (200 and 240 °C) to provide a basis for estimating the effect of temperature. An all-glass apparatus made it possible to produce vapors containing less than 1 mol-% of dioxygen, and it was demonstrated that this low oxygen concentration did not affect the precision of measurements. The viscosity can be represented by the equation

$$\mu = 134 + 0.35(t - 100) - 14y$$

where μ is the viscosity in μ Ps, t is the temperature in °C, and y is the mol fraction of H₂O₂. This equation is recommended for the calculation of the viscosity of vapor mixtures of H₂O₂ and H₂O over the temperature range of 373 to 573 K (100 to 300 °C) and is believed to have a precision of $\pm 2\%$.

3.7 Surface Tension of Hydrogen Peroxide

Density, surface tension, and viscosity measurements of highly concentrated hydrogen peroxide are difficult to perform due to the interference of tiny bubbles formed during the decomposition of the highly concentrated material. The surface tension data for H₂O/H₂O₂ mixtures for two different temperatures are summarized in Table 15.

The data from Table 15 are plotted in Figure 20.

Table 16 is more convenient because it contains data for even degree Celsius numbers. Most likely it was obtained by interpolating the Phibbs and Giguere data, since it also uses the same two temperatures.

Similar surface tension measurements at 273 and 291 K (0 and 18 °C) were measured already 100 years ago [218]. The units of the measurements reported there should be dyn/cm and not dyn.

Calculated/extrapolated thermal conductivity data for 98% HTP are summarized in Table 19, and data for 98% HTP and water are graphed in Figure 21 for a very wide temperature regime, up to very close to the critical point, including temperatures where HTP is sure to decompose. The critical point of hydrogen peroxide is not only critical in the sense of merging liquid and vapor states but is also critical in terms of its explosion hazard. The thermal conductivity behavior of hydrogen peroxide between its normal boiling point and its critical point may be similar to that of water.

3.9 Heat Transfer Coefficient of Hydrogen Peroxide

Hydrogen peroxide has very good heat transfer properties, which make it suitable as a coolant in regeneratively cooled rocket engines, as long as the flow velocity is kept up high enough, and as long as the heat soaking back after engine shutdown does not overheat the residual liquid in the cooling channels. Heat transfer tests with 98% H₂O₂ were carried out in CRES-316 tubes [241–243]. The threshold of explosive decomposition is also dependent on the type of the wall material because some metals may act as catalysts and will lower the threshold beyond which a thermal runaway situation will destroy the engine.

Contrary to other liquids, hydrogen peroxide does not have a range of nucleate boiling heat transfer. Once a certain heat flux is exceeded, the incipient decomposition immediately leads to a film boiling heat transfer situation. The heat transfer coefficient of 98% H₂O₂ is illustrated in Figure 22. Under the conditions of this test, the curve ends abruptly at 550 cal cm⁻² s⁻¹ because the cooling capacity disappears as the wall burns out.

Figure 22: Heat transfer to 98% H_2O_2 at 47.5 at and 20.5 m/s flow velocity. (Reproduced and modified from [242].)

Due to the good heat transfer properties of 90% H_2O_2 , this oxidizer has been used as a regenerative coolant in the North American Aviation AR-2 rocket engine (see *Encyclopedia of Hypergolic Bipropellant Combinations*) which was used in piloted jet fighters to give them a fast escape in critical situations.

Experimental heat transfer studies on 90% H_2O_2 solutions indicated that a high flux heat transfer, usually associated with boiling, was obtained from a 347 stainless steel surface to liquid 90% H_2O_2 as a result of the H_2O_2 decomposition [244]. This decomposition, which simulates film boiling by the liberation of gas bubbles at the heat transfer surface, is accelerated with each temperature increase of the surface. Under the conditions studied, heat transfer rates were obtained that could not be explained by forced convection and/or boiling heat transfer alone. Figure 23 illustrates the magnitude of this effect in terms of heat flux as a function of surface temperature.

Figure 24, based on the same set of data, shows the heat flux as a function of temperature difference between the heater wall and the liquid.

An extension of these studies to high fluid velocities and moderately high temperature differences showed that at high flow rates and high Reynolds numbers (where decomposition is limited by the short liquid residence time), the resultant heat transfer data agreed with that expected for forced convective heat transfer [245]. It was found that heat fluxes as high as $11.75 \text{ BTU in.}^{-2} \text{s}^{-1}$ (at liquid velocities of 80 ft/s) could

Figure 23: Heat flux to 90% hydrogen peroxide at low flow velocities as a function of surface temperature T_s . (Reprinted and modified from [245].)

Figure 24: Heat flux to 90% hydrogen peroxide as a function of temperature difference between the heater wall and the liquid. (Reprinted and modified from [245].)

be obtained with 90% H_2O_2 without complication by decomposition of the hydrogen peroxide. A least-squares fit of the heat transfer data obtained on 90% H_2O_2 resulted in the following expression:

$$(N_{\text{Nu}})_f = 0.0287(N_{\text{Re}})_f^{0.8}(N_{\text{Pr}})_f^{\frac{1}{3}}$$

which is the least-squares fit of the heat transfer data graphed in Figure 25.

In unpublished studies by Pratt & Whitney, heat transfer measurements in the forced convective region of both 90 and 98% H_2O_2 were reported. They were later reported also by McCormick at FMC and repeated by Constantine and Cain [246]. Peak heat fluxes of $7.80 \text{ BTU in.}^{-2} \text{s}^{-1}$ were measured for 90% H_2O_2 at fluid velocities of 41.3 ft/s. The results obtained for the peak heat flux of 98% H_2O_2 at 4.83 MPa (700 psia) and 20.3 m/s (66.8 ft/s) are shown in Figure 26.

Figure 25: Heat transfer to 90% hydrogen peroxide

Heat transfer to water (for comparison)

Heat transfer to liquid 90% hydrogen peroxide in comparison to that to water. (Reprinted and modified from [244])

The correlation of the data in 98% H_2O_2 (Figure 27 and 28), respectively, indicated better agreement of the data with the Dittus-Boelter relationship. The Dittus-Boelter equation is:

$$\text{Nu}_D = 0.023 \text{Re}_D^{0.8} \text{Pr}^n$$

where D is the inside diameter of the circular duct, Pr is the Prandtl number and $n = 0.4$ for the fluid being heated. It has been suggested, however, that some of the apparently low heat transfer coefficients may be due to scaling (oxidation) of heat transfer surfaces, creating a low conductivity barrier.

Figure 26: Heat flux versus inside wall temperature during heat transfer to 98% H₂O₂. (Reproduced and modified from Pratt & Whitney, as referenced by Constantine and Cain [246].)

The correlation illustrated in Figure 28 is based on the Sieder-Tate equation for the convective region in the form:

$$\text{Nu}_b = 0.027 \text{Re}_b^{0.8} \text{Pr}_b^{1/3} \left(\frac{\mu_b}{\mu_w} \right)^{0.14}$$

where Nu is the Nusselt number, Re is the Reynolds number, Pr is the Prandtl number, and μ is the viscosity. The results of this equation are shown as a solid line. The subscript b designates the properties at the bulk temperature, and the subscript w designates the properties at the wall temperature.

A study at Aerojet on the use of 98% hydrogen peroxide for regeneratively cooled rocket engines reported that during 18 experimental tests, heat fluxes up to 7.8 kW/cm^2 ($48.2 \text{ BTU in.}^{-2} \text{ s}^{-1}$) were achieved [247]. Some of these high-pressure heat-transfer experiments were conducted with both 90 and 98% H₂O₂. Electrically heated 4.8 and 6.3-mm (3/16 and 1/4-in.) diameter Inconel 718 and 4.8-mm (3/16-in.) diameter stainless steel test sections were used at pressures of 5.86 and 32.4 MPa (850 and 4700 psi) and at coolant velocities of 7.62 to 60.35 m/s (25 to 198 ft/s) and feed temperatures from 289 to 389 K (60 to 240 °F). Thirteen of these tests were burnout tests, in which the burnout or ultimate heat flux was evaluated in electrically heated round tubes by increasing the heat flux in increments, at a fixed flow rate and at fixed pressure con-

Figure 27: Correlation of Nusselt number versus Reynolds number during heat transfer to 98% H_2O_2 ; convective heat transfer region. (Reproduced and modified from Pratt & Whitney, as referenced by Constantine and Cain [246].)

Figure 28: Correlation of heat transfer to 98% H_2O_2 with Sieder-Tate equation; convective heat transfer region. (Reproduced and modified from Pratt & Whitney, as referenced by Constantine and Cain [246].)

ditions, until failure of the tube occurred. It was found that the heat flux at burnout (under the conditions tested) was directly proportional to the fluid velocity by the relationship:

$$\text{heat flux} = 0.21 \times \text{velocity}$$

These results indicated good correlation of heat flux and fluid velocity with the studies of Sanborn et al. [244] and [245]. The remaining 11 of the 98% H_2O_2 tests were extended-duration tests in which a constant heat-flux level was maintained for durations up to 10 min. During these tests, no appreciable difference in heat transfer could be associated with feed temperature, and no detectable decomposition was evident. Four similar tests with 90% hydrogen peroxide indicated no discernible differences from the results of the 98% H_2O_2 tests. Titration of the peroxide after short-duration testing indicated that little or no H_2O_2 decomposition had occurred in the test section. The short-duration burnout tests showed that the maximum burnout heat flux is directly proportional to coolant velocity and is insensitive to coolant pressure. As in the studies of Sanborn et al. [244] and [245], the Dittus-Boelter correlation was found to represent the data more closely than either the Colburn or Sieder-Tate relationships (Figure 29). The straight line in Figure 29 is represented by the equation

$$\text{Nu} = 0.023 \text{Re}_f^{0.8} \text{Pr}_f^{0.4}$$

Figure 29: Raw forced convection heat transfer data for 98% H_2O_2 based on film properties, entered into a graph with least square fit of Dittus-Boelter equation. (Reproduced and modified from [247].)

The Dittus-Boelter equation, where the subscript b indicates properties for the temperature of the bulk of the fluid,

$$\text{Nu}_b = 0.023 \text{Re}_b^{0.8} \text{Pr}_b^{0.4}$$

would yield a conservative estimate of heat-transfer coefficients for 98% H_2O_2 and was recommended for design purposes. Long-duration tests conducted at velocities of 15.24 to 45.72 m/s (50 to 150 ft/s) with Inconel 718 tubing indicated that the long-duration burnout heat flux is degenerated to about 65% of that demonstrated in short-duration tests. Titration of the peroxide after these tests indicated that minor H_2O_2 decomposition had occurred. It was concluded that 98% H_2O_2 would be an excellent regenerative coolant in rocket engine systems. The long-duration burnout problem at high pressure can be avoided by limiting the design burnout heat flux to about 65% of the short-duration burnout point. A potential transient cooling problem could exist during the shutdown of a regeneratively cooled engine.

The results of all these studies have shown that hydrogen peroxide has coolant properties comparable to those of water. Of course, the difficulty in its use as a regenerative coolant lies in the limited stability of the H_2O_2 at higher temperatures. As a result, various bulk liquid temperature limits have been suggested and established in the use of H_2O_2 as a regenerative coolant. These limits range from established maximum allowable temperatures of 380 K (225 °F) (with a 58 °C = 105 °F rise over inlet temperature) to suggested operating limits of 394 K (250 °F) (with red line conditions at 408 K = 275 °F); see also [248].

A MEMS microrocket engine using 98% liquid hydrogen peroxide and JP7 as propellants uses its propellants to regeneratively cool the combustion chamber and the nozzle. Although JP-7 has been proven to be an effective coolant under such conditions, hydrogen peroxide becomes unstable at high temperature and may explode, thus adding a critical constraint to the cooling scheme. To address this issue, heat transfer experiments in 95 μm inside diameter, 4 mm long, electrically heated stainless steel microtubes have been performed to define the stability limit and explosion condition associated with 98% hydrogen peroxide thermal decomposition [249]. Tests were conducted whereby heat transfer to the hydrogen peroxide was increased until an explosion occurred. For each test, prior to the explosion, an experimental forced convective heat transfer coefficient was obtained and compared to standard empirical correlations. Experimental results indicated that 98% hydrogen peroxide has limited cooling capacity for a regeneratively-cooled rocket engine. Independently of pressure and mass flow, results showed that a local fluid temperature of approximately 423 K (150 °C) consistently led to an explosion in stainless steel microtubes. In addition, standard macroscale heat transfer correlations were found to significantly underestimate the heat transfer rates obtained experimentally. Instead, a correlation developed for forced convective heat transfer in microtubes was derived and provided a more accurate estimate.

3.10 Refractive Index of Hydrogen Peroxide

Refractive index data are available for the entire concentration range from 0 to 100% H_2O_2 , but we are mostly interested in data for the upper concentration range. Table 20 gives the refractive index for the sodium D-line for hydrogen peroxide solutions in the range from 50 to 100% H_2O_2 . Similar data for a different temperature are in Table 21. Because refractive index can be measured even with relatively cheap refractometers accurately to the fourth place behind the decimal point, some tables give the conversion from refractive index to H_2O_2 concentration in increments of 0.2% H_2O_2 . We deemed the following table (Table 20) with 1% H_2O_2 increments sufficiently accurate for everyday use in a rocket propellant test site. One of our tables is for measurements at 293 K (20 °C), whereas tables in other sources (Schumb, Table 42, pages 269–270) are for 298 K (25 °C); 298 K (25 °C) may be more practical because in a laboratory it is easier to warm the sample to 298 K (25 °C) than to cool it to 293 K (20 °C) if the lab is located in a warm climate. On the other hand, 298 K (25 °C) is more likely to cause problems with bubble formation.

Other sources give the refractive index for light with other wavelengths, but we restrict ourselves to data that were obtained with the sodium D line (589 nm).

A 1943 publication [250] gave the refractive index for the C-, F-, and G-lines of hydrogen and the Na D line, first for pure H_2O_2 ($n_D^{20} = 1.4087$) and then over the whole range of concentrations in 0.2-% increments at four different temperatures (289, 293, 297, and 301 K = 16, 20, 24, and 28 °C), but the data were later revised. Previous values for the n_D of pure and aqueous H_2O_2 were revised owing to errors in analysis and in temperature control. The best value for anhydrous H_2O_2 now is $n_D^{25} = 1.4067 \pm 0.0001$, and it has an average temperature coefficient of $3.4 \times 10^{-5} \text{ °C}^{-1}$, as shown in [251].

For rocket applications, the main interest is in HP above 65% H_2O_2 , and we have not included refractive index data for H_2O_2 solutions below 50%. However, if one plots the included refractive index data for H_2O_2 solutions below 50%, one will notice that the curve has a kink (“dogleg”) and a change in slope between 20 and 40 mass-% H_2O_2 .

Hydrogen peroxide as a ligand in metal salts, replacing water of crystallization, alters the refractive index of these adducts [252].

3.11 Spectroscopic Properties of Hydrogen Peroxide

The absorption spectra of hydrogen peroxide are summarized in detail in this chapter because the spectroscopic properties of hydrogen peroxide are the basis of analytical methods and lead to a better understanding of the energy content and causes for decomposition of this unstable molecule. It is the energy content that makes this chemical useful as a rocket propellant. Understanding the molecular structure is important in explaining processes that lead to its formation (e.g., in quenching an O_2/H_2 flame) and its decomposition (thermal or catalytic processes). The excited states in a molecule, measured by absorption of infrared or ultraviolet energy, are just one step prior to dissociation (or even explosion), and the threshold of dissociation of H_2O_2 must be known in order to use it safely. There are several processes that lead to the natural occurrence of H_2O_2 . One of the typical methods for a spectroscopist is to compare spectra of hydrogen peroxide H_2O_2 to spectra of the isotope-substituted deuterium peroxide D_2O_2 . Isotope substitution is often helpful in identifying specific molecular vibrations in a molecule and the absorption frequency of spectra associated therewith. Therefore, we carry references to D_2O_2 , although it is not used as a rocket propellant. The search for higher (potentially more energetic) polyoxides H_2O_3 and H_2O_4 is also supported by spectroscopic evidence of the short-lived existence of these molecules.

Reactions of alkaline hydrogen peroxide with chlorine give atomic oxygen in an excited state that can power a chemical laser. Although no hydrogen peroxide is involved in the lasing, transitions between molecular energy levels of such processes releasing atomic oxygen need to be understood, based on the spectra of hydrogen peroxide summarized in this chapter.

3.11.1 IR and Raman Spectra of Frozen Hydrogen Peroxide

Spectra of hydrogen peroxide in the frozen state show the strong interaction of hydrogen bonds that are responsible for the high freezing point of this chemical. Isolating H_2O_2 molecules in a solid matrix of an inert, frozen, IR-transparent material will eliminate the interaction between adjacent molecules and result in sharper spectra.

The IR absorption between 2.5 and 25μ of thin films of pure frozen H_2O_2 has been measured at 4 and 80 K [192]. Two types of spectra were observed, one crystalline and the other amorphous. It was shown that the molecular spectrum of ordinary ice is not crystalline but vitreous. The spectra of frozen mixtures of H_2O_2 and H_2O deposited simultaneously from the vapor indicated large shifts of the intermolecular vibrations in the crystalline dihydrate, $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$. The principal intermolecular force constant in crystalline H_2O_2 was calculated to be $0.24 \times 10^5 \text{ dyn/cm}$.

The infrared spectrum of crystalline and vitreous hydrogen peroxide was studied from 300 to 4000 cm^{-1} , and a normal coordinate analysis of the tetragonal crystal with four molecules/unit cell showed that the hydrogen bonds are only slightly weaker than in H_2O , but the O—H line widths due to hydrogen bond broadening are only 80 cm^{-1}

[253]. From the coupled motion of the torsion and the high-frequency libration, the torsional frequency in the gas was estimated to be about 230 cm^{-1} .

Comparing the far IR spectra of H_2O_2 and D_2O_2 in the solid states, the absorption spectra of hydrogen and deuterium peroxides in the crystalline and glassy states were measured in the far IR down to 50 cm^{-1} [254]. All the lattice vibrations predicted by the group theory on the basis of the known structure of the crystal have been observed, but some previous assignments of the internal torsion and the high-frequency libration had to be revised. The new data confirmed that in the crystal, the H_2O_2 molecules are trapped in a strained configuration. The samples were always obtained first as glasses that showed no definite low-frequency bands. With deuterium peroxide two distinct metastable phases could often be observed.

A systematic investigation of the vibrational spectra of the hydrogen peroxide crystal and its deuterated analog over the range $4000\text{--}50\text{ cm}^{-1}$ has been carried out using both IR and Raman spectroscopy [255]. Mixtures of the two isotopic species up to approximately 95% deuteration were studied to identify the fundamentals of the hybrid molecule, HDO_2 . Single crystals of hydrogen peroxide oriented along two of the three crystallographic axes were examined in the Raman effect with polarized laser light. The O—H stretching bands were remarkably narrow in the Raman spectra: $\Delta\nu = 20\text{ cm}^{-1}$ at 80 K (-193°C) compared to about 80 cm^{-1} in the IR. Nearly all the O—H stretching components predicted by the factor group analysis were observed, but a satisfactory identification of all components of the OOH deformation modes could not be achieved. The O—O stretching frequency in D_2O_2 (872 cm^{-1}) was slightly higher than in H_2O_2 , (871 cm^{-1}) contrary to expectations. The hydrogen bonds in the H_2O_2 crystal appeared somewhat less strong (by about 10–15%) than those in ice. The low-temperature crystal $\text{H}_2\text{O}_2\text{-I}$ has a characteristic, intense O—O stretching mode at 880 cm^{-1} at 263 K. In addition, it has eight relatively strong lattice phonons and four O—H vibrons at 263 K. Two of the OH stretching modes at 3332 and 3198 cm^{-1} are strong, but the other two are weak side bands. The normal mode analysis found that the force constant of the O—H stretching mode in $\text{H}_2\text{O}_2\text{-I}$ is less than that of water ice, which implicates a weaker hydrogen bond strength in $\text{H}_2\text{O}_2\text{-I}$ than in ice.

3.11.2 Matrix-Isolated Hydrogen Peroxide

Isolating H_2O_2 molecules in a solid matrix of an inert, frozen, IR-transparent material will eliminate the interaction due to hydrogen bonding between adjacent molecules and result in sharper spectra.

Matrix-isolation spectra of the system $\text{H}_2\text{O}_2:\text{N}_2$ obtained in the region $4000\text{--}300\text{ cm}^{-1}$ at 4.2 K were free of complications due to association or over-all rotation [256]. The most unusual feature of these spectra was the band system at 385 and 350 cm^{-1} in the torsional region. This main band at 385 cm^{-1} was exceedingly broad for a matrix spectrum. These bands were then assigned to the $n = 0 \rightarrow 1$ and $1 \rightarrow 2$ torsional transitions.

The infrared spectrum between 4000 and 200 cm^{-1} of polycrystalline D_2O_2 at 83 K (-190°C) corresponded to that of H_2O_2 indicating that the crystal structure and coupling for each of the six normal modes are the same in D_2O_2 as in H_2O_2 [257]. At temperatures near 173 K (-100°C) the crystal spectra of both H_2O_2 and D_2O_2 changed with time on CsI and CsBr cold windows. The greatest change observed was that the crystal bands arising from torsion disappeared and were replaced by two other bands about 100 cm^{-1} lower in frequency. Also, the bands in the stretching and bending regions lost their fine structure and shifted to lower frequency, indicating that the peroxides actually dissolved into the salt windows without decomposition at these low temperatures. The spectra of H_2O_2 and D_2O_2 matrix isolated in argon and nitrogen at about 8 K showed that the most interesting features of these spectra are the extraordinarily broad bands in the torsional region, ν_4 , in both nitrogen and argon as the matrix.

The Raman spectra of solid hydrogen peroxide and deuterium peroxide were measured by the matrix-isolation technique in solid argon at 10 K [258]. The first three symmetric fundamentals were observed for peroxide monomers only. Correlation with existent infrared spectra lead to a reassignment of the latter in terms of hydrogen-bonded polymers. Some spectroscopic features and diffusion experiments suggested the existence of cyclic dimers, favored structurally. The products from a microwave discharge in D_2O vapor and argon were also examined by the same technique in infrared and Raman. Besides water and peroxide, some ozone and DO_2 radicals were found, as well as the unstable polyoxides, D_2O_3 and D_2O_4 ; the latter two, however, only at very small concentrations.

3.11.3 IR and Raman Spectra of Liquid Hydrogen Peroxide

The absorption spectrum of 99.6% pure liquid H_2O_2 has a wide diffuse band with a maximum at 10110 $\text{\AA}$. This represents a shift of 400 cm^{-1} from the frequency of the corresponding band of H_2O_2 vapor [259]. A low-temperature dihydrate phase was identified using infrared spectroscopy [192]. The low-resolution wide-band IR spectrum of liquid H_2O_2 is presented in Figure 30.

A high-dispersion study of the OH bands of hydrogen peroxide in the photographic infrared revealed the rotational structure of the two hybrid bands at 10283.68 and 10291.08 cm^{-1} [261]. The small moment of inertia of hydrogen peroxide was found to be $2.786 \times 10^{-40} \text{ g cm}^2$, while the harmonic mean of the two larger moments of inertia was found to be approximately $33.9 \times 10^{-40} \text{ g cm}^2$. The planar *cis* configuration was ruled out spectroscopically, and it was concluded that hydrogen peroxide exists in a non-planar form.

The IR absorption spectrum of H_2O_2 was reexamined in the region from 1.5 to 25 μm and compared to that of D_2O_2 [262]. Figure 31 shows IR absorption spectra of hydrogen peroxide solutions with three different concentrations in the range between 0.9 and 2.1 μm .

Figure 31: Infrared absorption spectra of aqueous hydrogen peroxide solutions. (Republished and modified from [262], with permission of © 1955 Canadian Science Publishing; permission conveyed through Copyright Clearance Center, Inc.)

A pair of well-resolved perpendicular bands arising from torsional oscillation of the OH groups was found centered about 460 and 575 cm^{-1} . The overtone band at 3.8 μm is a hybrid with prominent rotational structure and some indications of doubling. The vapor bands of D_2O_2 are quite different in appearance from those of H_2O_2 . Four new overtone bands were observed in liquid H_2O_2 . The infrared spectrum of D_2O_2 was measured for the first time in the solid and vapor states. The vapor bands were quite different in appearance from those of H_2O_2 . One of the fundamentals, the asymmetric O—D stretching at 2661 cm^{-1} , was resolved sufficiently to allow calculation of the rotational constants of the isotopic molecule. The O—O stretching vibration at 11 μ was too weak to be located definitely in the spectra of the gaseous peroxides. The bond distances and angles were given as $r(\text{O—O})$, $1.49 \pm 0.01 \text{ \AA}$; $r(\text{O—H})$, $0.97 \pm 0.01 \text{ \AA}$; $\alpha(\text{OOH})$, $100^\circ \pm 2^\circ$.

The IR absorption of thin films of pure H_2O_2 between 2.5 and 25 μm has been measured at 4 and 80° K [263]. Two types of spectra were observed, one crystalline and the other amorphous. The results were discussed in terms of hydrogen bonding and disorder with reference to the case of water ice. It was shown that the molecular spectrum of ordinary water ice is not crystalline but vitreous. The spectra of frozen mixtures of H_2O_2 and H_2O codeposited simultaneously from the vapor indicated large shifts

Figure 32: Infrared spectra of crystalline mixtures of H_2O - H_2O_2 at 80 K (note the change of scale at 2000 cm^{-1} .) (Reproduced and modified from [263], with permission from © 1969 Elsevier; permission conveyed through RightsLink.)

of the intermolecular vibrations in the crystalline dihydrate, $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$. Important changes take place in the spectra of both H_2O and H_2O_2 crystals when these compounds are deposited together. Whereas the internal vibrations were little affected (except for ν_4 of H_2O_2), the intermolecular frequencies underwent large downward shifts: from 850 to 765 cm^{-1} for ν_{R} of H_2O and from 656 to 535 cm^{-1} for ν_{A} of H_2O_2 (Figure 32). The new bands with lower frequencies are characteristic of the crystalline dihydrate $\text{H}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$ since they were the most intense in mixtures having intermediate compositions in the neighborhood of $\chi = 0.3$, while the crystalline bands of both pure components became weaker.

Raman spectra of liquid 99.5% H_2O_2 were obtained at 303 and 233 K ($+30^\circ$ and -40°C) and compared with the spectrum of 90% D_2O_2 at 233 K (-40°C), revealing three bands not previously reported [264], Figure 33. Their assignment to molecular vibrations, together with that of the previously known bands, helped to clarify the structure of these molecules. Raman spectra were also obtained for aqueous solutions at 303 and 233 K (30° and -40°C) over the entire range of concentrations. The results indicated that the addition of hydrogen peroxide to water leads to more extensive hydrogen bonding and an increased degree of order in the solutions; see also [265].

Figure 33: Raman spectrum of liquid hydrogen peroxide at 233 K, normal exposure. (Reproduced and modified from [4].)

3.11.4 IR Spectra of Hydrogen Peroxide Vapor

The absorption spectrum of hydrogen peroxide vapor was examined under low dispersion in the range $2\text{--}15\text{ }\mu\text{m}$ [260]. Four bands were observed at 3590 , 2630 , 1255 , and 877 cm^{-1} . The spectrum of the liquid also was measured between 2 and $21\text{ }\mu\text{m}$, and it showed five bands at about 3400 , 2780 , 1350 , 880 , and 550 cm^{-1} . The last

one, which seemed very diffuse, was presumably the torsional oscillation of the OH groups; as such it corresponds to a potential energy barrier of the order of 16.7 kJ/mol (4 kcal/mol). Under high dispersion, the second harmonic O—H frequency was found to consist of two identical hybrid bands at 7036.6 and 7041.8 cm⁻¹, of which the rotational constant for the ground state was in perfect agreement with that already found for the third harmonic band. The explanation given previously for the doublet character of the vibrational levels of hydrogen peroxide was further substantiated by these results. Based on interpretation of both vibrational and rotational data, the O—H distance in hydrogen peroxide appears to be slightly greater than that in water.

A complete vibrational analysis of hydrogen peroxide, using the IR spectral data of other authors, made use of symmetry coordinates [266]. The amplitude factors corresponding to each of the six normal modes of vibration were calculated. While some theories stated that there can be no flow of energy between the normal modes, other hypotheses assumed that there is a flow of energy between the normal modes of the molecule, some of which lead to dissociation.

3.11.4.1 Near IR Spectrum of Hydrogen Peroxide Vapor

Hydrogen peroxide IR absorption bands obtained with better than 0.2 cm⁻¹ resolution demonstrated both doubling due to internal rotation and effects due to the inertial asymmetry [267]. The ground-state rotational constants were found to be: $A' = 10.068$ cm⁻¹, $B'' = 0.8740$, and $C'' = 0.8384$. These parameters indicated a wide dihedral angle for H₂O₂, as shown in the following structure parameters: O—O bond = 1.475 Å, O—H bond = 0.950 Å, dihedral angle $\alpha = 119.8^\circ$, and OOH $\alpha = 94.8^\circ$. The constants were applied to the microwave data for H₂O₂ and the deuterated species. The ground-state splitting was found to be 11.44 cm⁻¹, and this number, used with torsion at 317 cm⁻¹, gave the barriers hindering internal rotation. They were $V_{cis} = 1300$ cm⁻¹ and $V_{trans} = 300$ cm⁻¹. Spectra of the O—H stretching fundamental region between 3480 and 3720 cm⁻¹ with many Q-branch lines and in the OOH bending fundamental region between 2510 and 2800 cm⁻¹ were shown in high-resolution detail.

Vibrational overtone predissociation spectroscopy, which detects the products of a unimolecular reaction initiated by overtone vibration excitation as a function of wavelength, is a method of studying highly vibrationally excited and readily decomposable molecules like H₂O₂. Spectra obtained by varying the excitation laser wavelength while keeping the probe laser tuned to interrogate a single product state, mirror the overtone vibration absorption spectrum of those molecules that decompose into the detected quantum state. Using this dual-beam technique to detect individual rotational states of •OH fragments from hydrogen peroxide excited in the regions of the third to the fifth •O—H stretching overtone (4νOH, 5νOH, 6νOH) revealed coarse and fine vibrational structures in the spectrum [268]. A statistical model of the unimolecular decomposition in combination with the vibration-torsion model of the absorption spectrum can explain the dependence of the overtone vibrational predissociation spectra on the rotational state of the •OH product.

The dissociation lifetimes during the overtone-induced dissociation of hydrogen peroxide were found to be on the order of picoseconds and comparable with statistical lifetimes, although energy redistribution is not complete [269]. It was concluded that overtone vibrational excitation features are negligibly lifetime-broadened by reaction.

Population inversion by supersonic expansion is a common technique in gas dynamic lasers (GDL). It would be nice if H_2O_2 by itself (without addition of alkali, chlorine, and iodine) could be used to drive a GDL. Vibrational overtone excitation spectra of both bound and predissociative states of hydrogen peroxide molecules cooled in a supersonic expansion were measured by detecting the decomposition product following excitation of an overtone vibration [270]. Spectra of bound states were obtained by a two-photon excitation technique in which a second photon excites the molecule from its bound vibrational overtone state to a dissociative state. The features in the bound state ($4\nu\text{OH}$) spectrum are 0.08 to 0.13 cm^{-1} wide, reflecting small inhomogeneous broadening, but those to the predissociative state ($6\nu\text{OH}$) are $1.5 \pm 0.3\text{ cm}^{-1}$ wide. This width corresponds to a lifetime of about 3.5 ps . Spectra of predissociative states were measured by detecting the decomposition product following excitation of an overtone vibration and compared to spectra of bound states obtained by a two-photon excitation technique in which a second photon excited the molecule from its bound vibrational overtone state to a dissociative state.

The infrared spectrum of hydrogen peroxide can be successfully analyzed by assuming that the low-frequency torsional motion is adiabatically separable from the higher frequency stretching and bending motions in the molecule. This can be done by studying the coupling of torsion and OH overtone vibrations in hydrogen peroxide by high level *ab-initio* calculations [271]. The *trans* barrier and equilibrium torsional angle were calculated as a function of OH stretch and averaged overtone local-mode wave functions.

The absorption spectra of vapors of concentrated hydrogen peroxide/water mixtures (without a carrier gas) were characterized at wavelengths from 1390 to 1470 nm using a near-infrared diode laser [272]. Low pressures in a flow-through cell were used to examine spectral features near the Doppler-broadened limit. An advantageous portion of the spectra near 1420 nm containing several distinct H_2O_2 peaks and one well-known H_2O peak (for calibration) was identified, and the cross-sections of these peaks were determined. These cross-section values can be used to measure vapor-phase concentrations of H_2O_2 in propulsion, atmospheric chemistry, and sterilization applications; see also [273].

3.11.4.2 Far IR Spectra of Hydrogen Peroxide

In one of the first studies to extend the range of measurements to longer wavelengths, the absorption of H_2O_2 between 15 and 150 cm^{-1} was examined with a grating spectrometer with 0.3 to 0.5 cm^{-1} resolution [274]. One interpreter of the strong lines (a series of doublets) proposed that H_2O_2 is a nearly symmetric top with the K levels split by the hindered rotation potential barrier [275]; see also [267].

The torsional oscillation between the two OH groups of the hydrogen peroxide molecule was investigated by measuring the far-infrared absorption spectrum of the molecule [276]. A 1-m-focal-length vacuum grating monochromator was used to scan the region from 15 to 700 cm^{-1} with an average resolution of 0.3 cm^{-1} . A steady stream of H_2O_2 vapor was passed through the flow cell to avoid the interference from water formed as a decomposition product of H_2O_2 . The observed spectrum contained seven perpendicular-type bands of which only the Q branches were resolved. The centers of the seven bands were at 11.43, 116.51, 198.57, 242.76, 370.70, 521.68, and 557.84 cm^{-1} . These bands result from transitions between different states of the internal rotation, and their identification now makes it possible to assign the internal-rotation energy levels for the first five excited states. Relative to the torsional ground state, these levels occur at 11.43, 254.2, 370.7, 569.3, and 775.9 cm^{-1} . These data support a theory of internal rotation in the hydrogen peroxide molecule for use in the analysis of the far-infrared spectra. The rotational states were compared to those derived from microwave spectra.

The rotational barriers in the deuterium peroxide D_2O_2 molecule were investigated from the far-infrared absorption of the vapor and compared to those previously obtained for H_2O_2 [277]. A 1-m focal-length vacuum grating spectrometer was used to scan the region from 20 to 400 cm^{-1} with an average resolution of 0.4 cm^{-1} . Seven perpendicular-type hindered-rotation bands characterized by prominent Q branches and unresolved P- and R-branch structure were observed in the spectrum. The band centers were located at 1.88, 42.3, 123.5, 136.8, 206.7, 250.9, and 302.6 cm^{-1} . From these data, it was determined that, relative to the ground state, the first five excited hindered-rotation states are at 1.88, 208.6, 250.9, 387.7, and 511.2 cm^{-1} . A theory of internal rotation, developed for an earlier application to the far-infrared spectrum of hydrogen peroxide, was then applied to the D_2O_2 spectrum. For this potential function, the *cis* and *trans* potential barrier heights are 2470 and 377 cm^{-1} , respectively, and the potential minima are 110.8° from the *cis* configuration. These parameter values are similar to the corresponding H_2O_2 values of 2460 cm^{-1} , 386 cm^{-1} , and 111.5°.

Using high-resolution Fourier transform spectra (resolution: 0.002 cm^{-1}), it was possible to measure the relative intensities of lines in the far-infrared spectrum of H_2O_2 in the 25–400 cm^{-1} spectral region [278]. The value of the dipole moment obtained from the fit of the observed intensities was then scaled to the value obtained from Stark effect measurements. A synthetic spectrum of the far infrared band of H_2O_2 was generated for comparison, using the dipole moment determined in this work for the line intensities and the parameters and the Hamiltonian matrix for the line positions. In addition to the ($\Delta n = \pm 1$, $\Delta K a = \pm 2$) torsional-rotational resonances within the ground vibrational state, which are usually observed for H_2O_2 , the Hamiltonian model explicitly takes into account both the vibration-rotation resonances involving the ground state and the $\nu_3 = 1$ vibrational state and the “staggering” effect which is due to the *cis* potential barrier.

3.11.4.3 IR Spectra of Decomposing Hydrogen Peroxide

The hydroperoxyl radical $\text{HOO}^\bullet$ formed in decomposing hydrogen peroxide can be identified not only by EPR and photoionization spectroscopy but also through its infrared spectrum [279].

3.11.5 Microwave Spectra of Hydrogen Peroxide

At the far end of the infrared spectral range, absorption spectra overlap with microwave spectra. Both are used to characterize the hydrogen peroxide molecule. In special applications, microwave heating can be used to ignite hydrogen peroxide by itself or in combination with combustible fuels.

Nine absorption lines of H_2O_2 and one hundred absorption lines of D_2O_2 and HDO_2 have been observed in the microwave frequency region using a flow system for sampling to overcome the decomposition of the peroxide at low vapor pressure [280], Table 22. An analysis of the microwave spectrum of H_2O_2 , using a symmetric top approximation, revealed that it is necessary to invoke hindered internal rotation to explain the experimental data. Using a sinusoidal approximation for the hindering potential yields a rotational barrier height of about 113 cm^{-1} . From Stark effect calculations, a dipole moment of 2.26 Debye units was obtained.

Table 22: Microwave absorption spectrum of hydrogen peroxide vapor.

Line	Frequency, Mc/s	Remarks
1	14829.5 ± 0.2	Quadratic Stark effect $J^* = 1$
2	37517.6 ± 0.2	Quadratic Stark effect $J^* = 2$
3	22054.5 ± 0.2	Quadratic Stark effect $J^*_{\min} = 7$, $ D = 1$
4	27639.6 ± 0.2	Quadratic Stark effect $J^*_{\min} = 7$, $ D = 1$
5	11072.4 ± 0.5	Quadratic Stark effect probably high J
6	35916 ± 2	Quadratic Stark effect high J , $ D = 1$
7	390333 ± 2	Probably high J
8	39495 ± 2	Probably high J
9	39790 ± 2	Probably high J

All lines are of medium or strong intensity, except 5, 6, and 7, which are relatively weak

Data source: [280]

Despite the excellence of theoretical models and the large amount of IR data that were available as of 1969, none had undergone the rigorous test offered by the high resolution of microwave spectroscopy. Until then, only two transitions of the ground vibrational state of HOOH had been measured and positively identified in the microwave region. Fifty rotational transitions of HOOH in the ground vibrational state have been measured in the millimeter-wave region from 60 to 300 kilomegacycles per second (kMc/s) and compared to similar measurements with DOOD [281]. Analysis of these transitions provided a complete set of values of the rotational constants and the accu-

rate value of $342\,885.0 \pm 2.0$ Mc/s for the doublet splitting of the ground-state vibrational levels by internal barrier tunneling. The rotational constants in the Hamiltonian for the semirigid-rotor model with an internal axis of rotation are (in megacycles per second): $\nu_{01,2}^{01,2} = 276208.0 \pm 2.0$, $\nu_{03,4}^{03,4} = 275912.7 \pm 2.0$, $\beta_{01,2}^{01,2} = 25662.1 \pm 2.0$, $\beta_{03,4}^{03,4} = 25673.7 \pm 2.0$, $\gamma_{01,2}^{01,2} = 542.96 \pm 0.5$, $\gamma_{03,4}^{03,4} = 476.64 \pm 0.5$. The dihedral angle of the OH bonds was found to be $120^\circ 1' \pm 15'$ for the lower level and $116^\circ 7' \pm 15'$ for the upper level of the ground-state doublet. Analysis of the millimeter-wave spectrum of HOOH provided a value of 342885.0 ± 2.0 Mc/s for the splitting of the ground vibrational state via the barrier tunneling mechanism.

The millimeter and submillimeter wave spectra of hydrogen peroxide have been extended to include the first excited torsional state, $n = 1$ [282]. The 135 newly assigned rotational transitions within the $n = 1$ torsional state ranged from $Ka = 2$ to 9 and up to $J = 30$. Sixty-seven new observations in $n = 0$, which included rotational quantum numbers up to $J = 47$ and $Ka = 5$, supplemented the previously measured 349 torsional ground state transitions.

3.11.6 UV Spectra of Hydrogen Peroxide

Hydrogen peroxide and peroxyacetic acid play an important role in the smog formation in the polluted atmosphere. Under the influence of sunlight in the atmosphere, hydrogen peroxide both forms and decomposes, and during its brief lifetime reacts with other species in the atmosphere, forming more persistent smog contributors such as peroxyacetic acid or peroxyntiric acid. The significance of peroxyntiric acid formation in photochemical smog has been the subject of many publications. Peroxyntiric acid would be a good rocket propellant oxidizer but is unfortunately too unstable for that application. Not only on Earth but also on other planets and some of their moons may the photochemical formation of and photolysis of hydrogen peroxide play an important role. The strong ultraviolet radiation on the surface of Mars most likely causes a high content of hydrogen peroxide in the ice in the polar caps. Traces of hydrogen peroxide have been detected in the Martian atmosphere. The photochemical production of hydrogen peroxide has been proposed previously as the primary mechanism for the oxidizing nature of the surface of Mars. The UV spectra of hydrogen peroxide are also of interest for UV-sterilization of drinking water.

It is extremely difficult to obtain clean UV absorption spectra of H_2O_2 vapor because the labile chemical photolyzes and decomposes before the recording of a spectrum is finished, and the spectrum becomes contaminated by decomposition products. Hydrogen peroxide UV spectra must be taken in flow cells where the supply of analyte is constantly renewed.

Although other investigators stated that they were unable to observe a sharp cut in the absorption spectrum of hydrogen peroxide vapor [283], it was later shown that there is a rather abrupt increase of the absorption coefficient at $1920\text{ \AA}$ [284]. It is doubtful that the dissociation energy of hydrogen peroxide can be derived from its

absorption spectrum. However, it seems possible that the photochemical decomposition of hydrogen peroxide gives an upper limit for its dissociation energy. There is no sharp cut of the absorption coefficient in the region of 2000 to 2100 Å. The absorption of hydrogen peroxide, with and without presence of water vapor, was measured at room temperature and slightly higher temperature. Because the beam of UV that is supposed to analyze the H_2O_2 vapor also decomposes the chemical, a steady stream of fresh, undecomposed H_2O_2 vapor must be flowed through the absorption cell in the spectrometer. The supply of liquid 100% pure hydrogen peroxide was kept in a quartz vessel evaporator at constant temperature. The quartz vessel was connected with one end to the absorption cell made of quartz, which was 190 cm long and 3 cm wide. The other end of the cell led to a liquid air-cooled trap and then to a vacuum pump. The hydrogen peroxide vapor flowing through the cell was collected in the cooling trap and then analyzed.

The ultraviolet absorption spectra of H_2O_2 in water and D_2O_2 in heavy water between 3000 and 4000 Å were measured at various concentrations [285]. Both peroxides showed slight but real deviations from Beer's law at high concentrations. Replacement of H by D shifts the absorption continuum by about 390 cm^{-1} towards shorter wave lengths. The shift is of the same order as that predicted from the difference in zero-point energy of the two isotopic materials.

The absorption coefficients of hydrazine and hydrogen peroxide between 1200 and 1400 Å were determined with a 2.5 Å bandwidth monochromator [286]. The absorption cross sections of hydrogen peroxide vapor in the wavelength range from 195 to 350 nm were determined at 296 K [287]. The absorption cross sections of neutral aqueous solutions of hydrogen peroxide were also measured in the same wavelength range to obtain calculated photodissociation coefficients of atmospheric hydrogen peroxide.

A superposition of ultraviolet absorption measurements published by ten different authors is shown in Figure 34. The shape of the curve relating the extinction coefficient to the wavelength in Figure 34 seems to be parabolic. Over a considerable range of wavelengths near the visible range the curve might be represented by a linear relationship on a semilogarithmic plot. It was suggested that a maximum in the absorption curve may well exist at wavelengths much shorter than those that have been investigated.

The UV spectra of frozen solutions of 17.5-M solutions of H_2O_2 in water at 265–320 nm were obtained as the difference between the spectrum of this solution and that of water, both frozen with liquid nitrogen [288]. The spectra of liquid and solid solutions of 17.5-M H_2O_2 in water were identical in this region.

The UV absorption cross sections of H_2O_2 vapor were determined over the wavelength range 210–350 nm at 296 K [289]. At the longer wavelengths, the gas-phase absorptivities were significantly larger than the corresponding values in the condensed phase. The atmospheric H_2O_2 photodissociation rate for overhead sun at the Earth's surface was estimated as $\sim 1.3 \times 10^{-5}\text{ s}^{-1}$.

Figure 34: Comparison of ultraviolet absorption molecular extinction coefficients of hydrogen peroxide vapor and solutions. (Reproduced and modified from [4].)

Note: The identification of the authors responsible for the different symbol data points in this figure has been removed. It is irrelevant for our application.

Ab-initio calculations at the SCF and CI levels were performed in order to assign the vibrational structure of the UV spectrum of hydrogen peroxide and explain the potential energy surfaces of the lower excited states [290]. The theoretical intensity curve including the vibrational excitations was then calculated using the harmonic oscillator potential model, and several new assignments of the vibrational levels of the UV spectrum were proposed.

Near-ultraviolet and visible absorption cross sections of H_2O_2 were measured using incoherent broadband cavity-enhanced absorption spectroscopy [291]. The highly sensitive measurements spanned the range of 353–410 nm and extended electronic absorption cross sections by 60 nm to absorption cross sections below $1 \times 10^{-23} \text{ cm}^2$

molecule⁻¹. The data now enables one to calculate photolysis rate constants for H₂O₂ and hydroxyl radical ([•]OH) production rates in the lower troposphere. See also [292].

In pure solutions, hydrogen peroxide concentrations can be determined directly from the optical absorbance. The molar extinction coefficients of H₂O₂ solutions in the ultraviolet at four different wavelengths of 245, 240, 235, and 230 nm are [293]:

$$245 \text{ nm} = 0.0308 \pm 0.0003$$

$$240 \text{ nm} = 0.0394 \pm 0.0002$$

$$235 \text{ nm} = 0.0500 \pm 0.0006$$

$$230 \text{ nm} = 0.0624 \pm 0.0013$$

3.12 X-Ray Photoelectron Spectra of Hydrogen Peroxide

The He I photoelectron spectrum of hydrogen peroxide showed a splitting of 1.0 eV between the first two bands due to the oxygen non-bonding orbitals [294]. CNDO/2 and *ab-initio* calculations on hydrogen peroxide indicated that the non-bonding orbital splitting as well as the orbital assignment depend largely upon the dihedral angle between the two halves of the molecule [295]. The photoelectron bands may be assigned to the $4b\{n - (O)\}$, $5a\{n + (O)\}$, $4a\{\sigma(O-O)\}$, $3a\{\sigma + (O-H)\}$, and $3b\{\sigma - (O-H)\}$ orbitals in this order, where the + and - combinations indicate symmetric and anti-symmetric combinations with respect to the C₂ axis. These orbital assignments were supported by consideration of a sum rule concerning vertical ionization energies.

Ab-initio calculations at the SCF and CI levels were performed to calculate the potential energy surfaces and stable conformations of the first two ionic states of hydrogen peroxide (H₂O₂⁺) [296]. The lowest ionic state 2B was found to be most stable in the *trans* conformation. The second lowest state is the 2A state and it is stable in the *cis* conformation. The agreement between a theoretical intensity curve and a measured photoelectron spectrum was satisfactory.

Photoionization spectroscopy can identify not only the undissociated H₂O₂, but also one of its fragments, the hydroperoxyl radical HO₂[•] [297].

3.13 Nuclear Magnetic Resonance Spectra of Hydrogen Peroxide

The NMR transverse relaxation time T_2 of aqueous H₂O₂ solutions depends on the rate of exchange of the spin-bearing protons between H₂O₂ and H₂O molecules. For pulse separations exceeding the inverse exchange rate, this value becomes a constant, depending only on proton exchange time and magnetic field strength. This exchange time depends in a non-analytical way on the concentration of H₂O₂ and on the pH value. Thus, a measurement of T_2 and pH allows the inversion of the data for the non-invasive quantitative determination of the H₂O₂ concentration [298].

3.14 Electron Paramagnetic Resonance Spectra of Hydrogen Peroxide Decomposition

Electron paramagnetic resonance studies were carried out in a rapid flow mixing chamber in order to determine the rate constants for some dozen initiation and propagation reactions of these highly transient intermediate species, many of which are free radicals [299].

3.15 Dielectric Constant of Hydrogen Peroxide

The dielectric constant (also called dielectric strength) of pure H_2O_2 is less than that of water at all temperatures. The dielectric constant of H_2O_2 - H_2O mixtures goes through a maximum at 65 mass-% H_2O_2 as illustrated in Figure 35. For this reason, the dielectric constant is not suitable as an analytical tool to measure the concentration of H_2O_2 in binary H_2O_2 / H_2O mixtures (using the refractive index would be a better choice). The dielectric constant changes moderately steeply between 70 and 100 mass-% H_2O_2 , where it drops from 82 to 73 [300].

Figure 35: Dielectric constant of hydrogen peroxide/water mixtures at various temperatures. (Reproduced and modified from [4].)

The dielectric constant of pure H_2O_2 as a function of temperature can be calculated from the following curve-fitted equation

$$\varepsilon = 84.2 - 0.62t + 0.0032t^2$$

where ε is the dielectric constant (dimensionless), and t is the temperature in $^{\circ}\text{C}$. Dielectric constant data for three different H_2O_2 concentrations, all near or above 90%, are given in Table 23.

Table 23: Dielectric constant of hydrogen peroxide solutions.

Temperature		H_2O_2 concentration, mass-%		
$^{\circ}\text{C}$	K	90% H_2O_2	98% H_2O_2	100% H_2O_2
-30	243	111		106
-20	253	103		98
-10	263	95		91
± 0	273	89		85
+10	283	82		79
+20	293	77	74	73
+30	303	72		69

Data source: Laporte Chem. and [27]

Hydrogen peroxide, like hydrazine or water, has a tendency to supercool when cooled to below the freezing point. The molecular structure of supercooled liquids has been studied by measuring the relaxation time and dielectric constants [301].

3.16 Dipole Moment of Hydrogen Peroxide

The dipole moment of H_2O_2 is 2.26×10^{-18} esu (Schumb, page 314). The non-zero dipole moment rules out the linear chain trans form and the planar trigonal configuration of the hydrogen peroxide molecule and speaks in favor of the skewed configuration (see the discussion on molecular structure in Section 3.20 below).

The electric moment of hydrogen peroxide was found to be 2.13×10^{-18} in dioxane [302]. Comparative measurements made on the electric moment of water in the same instrument gave 1.90×10^{-18} in dioxane. Measurements made with both water and hydrogen peroxide in ether gave lower values for their electric moments.

The dipole moment of H_2O_2 is in good agreement with a symmetrical formula for the molecule with an angle of 110° between the O and H atoms and free rotation of the two OH groups around the O—O axis [303].

From microwave spectra and Stark effect calculations, a dipole moment of 2.26 Debye units was obtained [304]; see also [305, 306].

3.17 Electrical Conductivity of Hydrogen Peroxide

Hydrogen peroxide is a very weak electrolyte, and the amount of autodissociation is like that of water. Since the electrical conductivity of water is also very low, it requires extremely pure water to determine the natural conductivity that is due only to autodissociation and not affected by dissolved electrolytes.

Like water, hydrogen peroxide is a very good solvent, favoring dissociation of many dissolved electrolytes, many introduced as contaminants, in all ranges of concentration.

Because so many metals catalyze the decomposition of hydrogen peroxide, it is difficult to find electrode materials for electrochemical methods that will not cause decomposition of the H_2O_2 sample. Tin electrodes have been used for various laboratory experiments of electrical conductivity.

Because the electrical conductivities of pure H_2O_2 and pure water are not very different, and because the measurements are so easily disturbed by contaminants (stabilizers) commonly found in hydrogen peroxide, electrical conductivity measurements are not suitable as an analytical method to quickly determine H_2O_2 assay in propellant samples in the field. Using the refractive index would be a more reliable method.

Electrical conductivity in the $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ system goes through a maximum at 50 mass-% H_2O_2 , as illustrated in Figure 36, which is a composite of data obtained from three different sources. These measurements were made on freshly distilled H_2O_2 samples. Roth and Shanley [307] measured a specific conductance of $3.9 \times 10^{-7} \Omega^{-1} \text{cm}^{-1}$ for the purest H_2O_2 sample they were able to obtain.

Figure 36: Specific conductance of hydrogen peroxide/water solutions at 298 K. (Reproduced and modified from [4].)

The specific conductance of hydrogen peroxide solutions with H₂O₂ concentrations above 80 mass-% is tabulated in Table 24.

Table 24: Specific conductance of hydrogen peroxide/water solutions at 298 K.

Mass-% H ₂ O ₂	Electrical conductivity at 298 K = 25 °C, Ω ⁻¹ cm ⁻¹ × 10 ⁻⁶	Source	Year	References
100	0.5	Bloom and Brunsvold	1957	[239]
98	0.8			
90	1.9			
99.9	0.39	Roth and Shanley	1953	[307]
98.5	0.82	Schumb	1949	[308]
80	3.4			

Measurements reported by the Laporte Laboratory in England showed a “flat maximum” in the curve of conductivity versus concentration extending over an appreciable range of concentration. This was not confirmed in later measurements, where samples of Becco 90% H₂O₂ were evaporatively redistilled at low pressure. The concentrated solutions were diluted with triply distilled “conductivity water” to the desired concentrations. Measurements of the specific conductivity were made at 288 K (15°C) in a conductivity cell with tin electrodes. The results of these measurements are indicated in Figure 37, which does not indicate any pronounced “flat maximum”, although the change in specific conductivity for the range 33–60 mass-% H₂O₂ is only from 4.0 to

Figure 37: Electrical conductivity of hydrogen peroxide/water solutions at 288 K. (Reproduced and modified from [309].)

$4.5 \times 10^{-6} \text{ ohm}^{-1} \text{ cm}^{-1}$. These results indicate that the form of the curve originally presented [308] is correct, although the maximum values in the vicinity of 50% H_2O_2 may be revised downward slightly.

Solutions of hydrogen peroxide in nitric acid are unstable when the concentration of the latter is greater than 50% HNO_3 . The conductivities of nitric acid solutions with <50% HNO_3 in water and water-peroxide mixtures have been determined, and the results indicated the formation of one or more unstable peroxides or peracids that are apparently incapable of ionizing [310].

Commercial as-received 90% H_2O_2 had an electrical conductivity of 11.5 μMHO . Purification by crystallization and a single distillation brought the conductivity down to 1.8 μMHO [311].

3.18 Magnetic Susceptibility of Hydrogen Peroxide

When a substance is placed in a magnetic field, the intensity of the field that passes within the substance may be either larger or smaller than the intensity of the field in the space surrounding the substance. A quantity called *permeability* is defined, which is a measure of the tendency of a magnetic field to pass through a substance as compared to the tendency to pass through a vacuum. Substances, such as oxygen, which are more permeable than a vacuum and in which a magnetic field becomes concentrated are termed *paramagnetic*. Substances, such as water and hydrogen peroxide, which are less permeable than a vacuum and in which a magnetic field is weakened are termed *diamagnetic*. Paramagnetic substances possess a permanent magnetic moment and are attracted to the more intense region of an inhomogeneous magnetic field, whereas diamagnetic substances acquire an induced magnetic moment when placed in a magnetic field and tend to be expelled from an inhomogeneous field. Hydrogen peroxide, like water, is diamagnetic.

When exposed to a strong magnetic field, both water and hydrogen peroxide were displaced in the same direction, that is, expelled from the field. Taking $K_{\text{H}_2\text{O}}$ as 7.2×10^{-7} and K_{air} as 0.25×10^{-7} , $K_{\text{H}_2\text{O}_2}$ was to have a value of 8.8×10^{-7} , as calculated in [312]. Thus, hydrogen peroxide is diamagnetic, and that to a greater extent than water.

Schumb 1953, [4], Ch. 5, p. 105–109 evaluated data for magnetic susceptibility of H_2O_2 solutions and nearly anhydrous H_2O_2 from four different sources and singled out the data for the magnetic susceptibility of pure H_2O_2 at 291 K (18 °C) measured by Gray and Farquharson [313, 314] as the most reliable set of data:

$$\chi_{\text{m}} = -(16.73 \pm 0.20) \times 10^{-6} \text{ cgs-units/mol}$$

Only a few updates to this data set have been published in the interim. A graph comparing the magnetic susceptibility data from different sources is shown in Figure 38.

Figure 38: Comparison of magnetic susceptibility of hydrogen peroxide data from four different sources. (Reproduced and modified from [4].)

If one assumes that susceptibility is a linear function of the composition of H₂O₂/H₂O solutions and with no indication of a real deviation from linearity at hand for H₂O₂/H₂O solutions, the following equation was obtained by least squares fit from the data of Neiding and Kazarnovskii:

$$\chi_g \times 10^6 = -0.724 + 0.218w$$

where χ_g is the magnetic susceptibility in cgs-units/g and w is the mass fraction of H₂O₂. This equation is off by 0.004 cgs units/g for pure water, which closely represents the quoted precision of the data. Therefore, 0.004 might be reasonably added to the values calculated by the equation above. The mass susceptibility of a diamagnetic substance is, according to theory, independent of temperature.

3.19 Thermodynamic Properties of Hydrogen Peroxide

The most reliable sets of thermodynamic data for hydrogen peroxide are those available on the NIST Standard Reference Data Program Online Databases Chemistry – WebBook, which are updated periodically, and which have been downloaded and included in our summary of data. The other set of standard thermodynamic data for H_2O_2 vapor is in the JANNAF tables. There are some older summaries on the thermodynamic properties of H_2O_2 [315].

The thermodynamic properties of H_2O_2 and D_2O_2 were evaluated by a statistical method [316]. The partition function for the internal rotation was obtained from the summation of experimental internal rotational energy levels. The enthalpies of formation ΔH°_f (298.15 K) of $\text{H}_2\text{O}_2(\text{L})$ and $\text{H}_2\text{O}_2(\text{G})$ were reported as $-(44.88 \pm 0.02)$ and $-(32.54 \pm 0.04)$ kcal/mol, respectively. The enthalpy of formation ΔH°_f (298.15 K) for $\text{D}_2\text{O}_2(\text{L})$ was derived as $-(47.00 \pm 0.04)$ kcal/mol. From this ΔH°_f $\text{D}_2\text{O}_2(\text{L})$ 298.15 K value and the enthalpy of vaporization of $\text{D}_2\text{O}_2(\text{L})$, $\Delta H^\circ_{\text{evap}}$ (298.15 K) = (12.51 ± 0.05) kcal/mol, the enthalpy of formation at 298.15 K for $\text{D}_2\text{O}_2(\text{G})$ was obtained as $-(34.49 \pm 0.09)$ kcal/mol.

Partition functions of both rotational modes (hindered internal rotation and overall rotation) of the H_2O_2 molecule were considered to calculate the thermodynamic functions (internal energy, enthalpy, Helmholtz free energy, Gibbs free energy, and entropy) for a hydrogen peroxide gas of weakly interacting particles close to local thermodynamic equilibrium at temperatures above 300 K [317]. In such a gas, the functions may be obtained from the relationships of Gibbsian statistical mechanics.

3.19.1 Heat Capacity of Hydrogen Peroxide

3.19.1.1 Heat Capacity of Frozen Hydrogen Peroxide

The heat capacity of crystalline H_2O_2 , 99.97% pure, between 12 K and the melting point was determined with a low-temperature adiabatic calorimeter. The only anomaly in the heat capacity measurements was the absorption of 1.3 cal/mol at 216.8 ± 0.15 K, the lower eutectic temperature of H_2O - H_2O_2 solutions.

3.19.1.2 Heat Capacity of Liquid Hydrogen Peroxide

Heat capacity (specific heat) data of hydrogen peroxide and hydrogen peroxide solutions are summarized in Table 25.

Heat capacities were determined for $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures over the entire range of compositions for two temperature intervals starting at 298 K [318]. It was difficult to obtain accurate data at the upper end of the temperature range due to incipient decomposition. Table 26 gives smoothed data of the average heat capacities for $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures.

Table 25: Heat capacity (specific heat) of hydrogen peroxide and hydrogen peroxide solutions.

Phys- ical state	H ₂ O ₂ concen- tration	Temperature (range)		Heat capacity (specific heat), c_p		Source	Year	References

Earlier heat capacity determinations for pure H₂O₂ gave 21.35 cal °C^{−1} mol^{−1} = 0.6276 cal °C^{−1} g^{−1} [319]; see also [188, 320].

The practically most important hydrogen peroxide concentration for rocket applications is 90% H₂O₂. Heat capacity and other thermodynamic data for 90% H₂O₂ solutions are listed in Table 27.

Charts were presented for liquid and vapor heat capacities of hydrogen peroxide from 255 to 478 K (0 to 400 °F) [233].

Table 26: Smoothed data of the heat capacities for H₂O₂/H₂O mixtures.

H ₂ O ₂ , Mass-%	Mol fraction H ₂ O ₂	Avg. molecu- lar mass	Heat capacity c_p			
			cal g ⁻¹ °C ⁻¹		J g ⁻¹ K ⁻¹

3.19.1.3 Heat Capacity of Hydrogen Peroxide Vapor

The vapor phase heat capacity of H₂O₂ can be calculated from the Shomate equation:

$$C_p^\circ = A + BT + CT^2 + DT^3 + ET^{-2}$$

where A, B, C, D, and E are constants, and T is the absolute temperature in K divided by 1000. The coefficients are listed in Table 28. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation and the standard entropy of the vapor (Section 3.19.2 and 3.19.6). These equations were curve-fitted from data covering a range from 298 to 1500 K.

It was suggested that anomalies in the properties of supercooled water reflect the approach to a thermodynamic singularity in the vicinity of 228 K (–45 °C), and an attempt has been made to separate the total heat capacity of water into “anomalous” and “normal” components [321, 322]. The basis for such a separation is extrapolation to zero solute content of C_p of binary aqueous solutions from which the low-temperature anomalies have disappeared. The low temperature molar C_p isotherms of two closely related systems based on the second components H₂O₂ and N₂H₄ (N₂H₅OH) are very unusual. The extrapolations to zero solute of C_p isotherms in the two systems yielded similar but not identical “normal” components for pure water. The corresponding alternative sets of “anomalous” C_p components versus temperature data, when best-fitted to the singular point equation

$$C_{p(\text{anom})} = A(T/T_s - 1)^{-\gamma},$$

yield the same T_s value, 226 K.

Table 27: Thermodynamic data for 90% hydrogen peroxide solutions.

3.19.2.1 Enthalpy of Formation of Hydrogen Peroxide Vapor

The vapor phase excess enthalpy above the standard enthalpy of formation $\Delta H^\circ_{f,298}$ of H₂O₂ can be calculated from the Shomate equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - \Delta H^\circ_{f,298}$$

where A, B, C, D, E, and F are constants, and τ is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 28. The same coefficients (and others) were used for a formula expressing the heat capacity of the vapor (Section 3.19.1.3). These equations were curve-fitted from data covering a range from 298

Table 30: Thermodynamic properties of hydrogen peroxide vapor.

Data source: [33]

to 1500 K, according to [327]. The data in Table 30 were obtained from the same source and are consistent with the equation(s) above and below.

The thermodynamic functions of H_2O_2 vapor were calculated by Giguere [323] over the range from 298.16 to 1500 K based on structural data from the literature and determinations of the IR and Raman frequencies. The enthalpy of formation ΔH , the free energy of formation ΔF , and equilibrium constants at temperatures up to 1500 K were calculated for the formation of gaseous H_2O_2 from its elements, the decomposition of gaseous H_2O_2 into water vapor and oxygen, and the decomposition of H_2O_2 vapor into two hydroxyl-free radicals.

3.19.2.2 Enthalpy of Formation of Hydrogen Peroxide/Water Mixtures

In first approximation, enthalpies of formation of hydrogen peroxide/water mixtures could be calculated assuming additive behavior and neglecting the heat of mixing, which is small among compounds with similar molecular structure.

Enthalpies of formation for three hydrogen peroxide/water mixtures (50, 70, 90% H_2O_2) listed in the popular PROPEP/NEWPEP/GUIPEP Thermochemical Equilibrium program for the calculation of theoretical specific impulse of rocket propellants were unfortunately incorrect, and the mistake has persisted for almost 20 years. The three incorrect numbers shown in the PEPCODED.DAT 1986 file (-1927, -1684, and -1439 cal/g) should be replaced by the corrected numbers published a few years later. The correct enthalpies of formation for the three hydrogen peroxide/water mixtures were published in a very useful tutorial, and correction for NEWPEP and are -2556, -2070, and -1571 cal/g [328]. The number for the 90% H_2O_2 solution, -1571 cal/g, matches correctly with the number from Table 27 above.

3.19.3 Heat of Fusion of Hydrogen Peroxide

Enthalpies of the fusion data of solid hydrogen peroxide are summarized in Table 31.

Table 31: Enthalpy of fusion of hydrogen peroxide.

Temperature	cal/g	cal/Mol	kJ/Mol	Source	Year	References
K °C						
At the melting point	87.84	2987 ± 3	12.498	Giguere et al.	1954	[188]
At the melting point	85.83 ± 0.18	2919.5 ± 6.1	12.215	Foley and Giguere	1951b	[184]
For comparison: enthalpy of fusion of water						
273	0	79.72	1436.3	6.0095		
Molecular mass = 34.0147 g/mol = 29.399 mol/kg						

3.19.4 Heat of Vaporization of Hydrogen Peroxide

The heat of vaporization at the normal boiling point is 47.11 kJ/mol (11.26 kcal/mol = 331.2 cal/g) ([215], Ref. 26 in Schumb, page 231 and 304). From measurements of heat of vaporization of mixtures, those of pure H₂O₂ and D₂O₂ were calculated as 51.63 and 52.34 kJ/mol (12.34 and 12.51 kcal/mol), respectively [319]. The heat of vaporization of H₂O₂ at different temperatures is summarized in Table 32.

Table 32: Enthalpy of vaporization, 100% H₂O₂.

Data source: [318]

The heat of vaporization of $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures at four different temperatures was calculated from vapor pressure data over the entire range of $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ compositions (Table 33).

3.19.5 Heat of Solution and Heat of Dilution of Hydrogen Peroxide

The mixing of pure hydrogen peroxide with water and the dilution of H_2O_2 solutions with additional amounts of water are usually exothermic. The effect of dilution is mildly exothermic (negative ΔH) for all concentrations above 294 K (21 °C). Some dilution processes below this temperature are endothermic. It is important to know the exact enthalpy of formation of H_2O_2 solutions if one wants to calculate the theoretical performance of H_2O_2 solutions to be used in a steam generator or rocket engine. Simply assuming additive behavior of the enthalpies of formation of the two ingredients H_2O_2 and H_2O will result in substantial errors. It was noticed 20 years ago that even a very popular theoretical rocket performance calculation computer program had incorrect enthalpy data for 50, 70, and 90% H_2O_2 in its ingredients data base.

To clarify the nomenclature, the term *heat of solution* or *heat of mixing* is applied only if one starts out with 100% H_2O_2 and adds various amounts of pure water. The term *heat of dilution* is appropriate, for instance, if one takes a 90% H_2O_2 solution and adds more additional water, e.g., in order to lower the flame temperature of a rocket engine.

All solution or dilution processes with hydrogen peroxide and water are exothermic when carried out above 294 K. Strangely enough, performing these operations at lower temperature has little thermal effect or is even endothermic. This is probably

an effect of breaking up the water clusters as one approaches the point of the highest density of water at 277 K. Hydrogen peroxide does not have a density maximum in the liquid range as water does. The heat capacities of the two liquids and their mixtures diverge in the same area.

In tabulating heats of solution and heats of dilution, there are two numbers that the experimenter will need to predict the exothermicity of the process and to correct for non-additive behavior of the enthalpies of formation in binary mixtures. The two numbers are **(1)** the integral heat of solution for the process of mixing anhydrous H_2O_2 with H_2O to form a solution with a given H_2O_2 concentration, and **(2)** the heat of dilution to infinite dilution.

In addition to using heat of dilution and heat of solution data for calculating the enthalpy of formation of H_2O_2 solutions (which are needed for many rocket performance calculations), the numbers are also needed to calculate the energy requirements for an industrial peroxide distillation and concentration plant. It takes energy to separate H_2O_2 and H_2O from their mixtures.

Table 34: Heats of dilution of hydrogen peroxide solutions in water at two different temperatures.

Data source: [319]

Since the heat of dilution or heat of solution can be either endothermic or exothermic, the sign preceding the number can be either positive or negative. By convention, if the system is giving off heat to its environment, the process is exothermic, and the polarity of the enthalpy is negative. In using heat of dilution data, one must be careful to use the proper prefix (positive or negative); see also [194].

Table 34 gives the data that were also used to draw the graph in Figure 39.

Figure 39 shows that at lower temperatures the dilution of certain H_2O_2 solutions can become an endothermic process (based on data by [319] = Schumb's Ref. 79).

Figure 39: Integral heat of solution of hydrogen peroxide in water. (Reproduced and modified from [2].)

Table 34 gives only raw experimental data, but the integral heats of solution that are derived therefrom by interpolation and summarized in Table 35 are more useful.

The heat of **mixing** of H_2O_2 in H_2O at 298 K (25°C) and infinite dilution is -3427 J/mol (-819 cal/mol) [329]. The heat of mixing of H_2O_2 is $-3427 \pm 8 \text{ J/mol}$ ($-819 \pm 2 \text{ cal/mol}$), but that of D_2O_2 is $-3376 \pm 8 \text{ J/mol}$ ($-807 \pm 2 \text{ cal/mol}$).

Graphical representations of the heat of mixing of propellant-grade H_2O_2 - H_2O solutions were plotted from smoothed data given by [318]. These data agreed quite well with previous experimental data. Figure 40 was drawn using data from earlier publications based on data from Giguere and Carmichael [318].

Table 35: Integral heat of solution and heat of dilution to infinite dilution for hydrogen peroxide and water.

Figure 40: Heat of mixing of hydrogen peroxide and water. (Reproduced and modified from [246], based on data from [318].)

3.19.6 Entropy of Hydrogen Peroxide

One of the first measurements of the entropy of H_2O_2 as an ideal gas at 1 atm and 25 °C gave $55.76 \pm 0.12 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1} = 233.3 \pm 0.5 \text{ J mol}^{-1} \text{ K}^{-1}$ [188], as listed in Table 36. Comparison of this value with a recalculated statistical entropy leads to a value of $3.5 \text{ kcal/mol} = 14.6 \text{ kJ/mol}$ for the height of a hypothetical single barrier hindering internal rotation in the molecule. It was concluded that H_2O_2 does not consist of two tautomeric modifications.

Table 36: Entropy of hydrogen peroxide.

State	Temperature	Entropy		Source	Year
	K	$\text{cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$	$\text{J mol}^{-1} \text{ K}^{-1}$		
Vapor at 101 kPa = 1 bar	298.15		232.95	[324]	1960
Vapor at 101 kPa = 1 bar	298.15		234.542	[330]	2003
Ideal gas at 101 kPa = 1 bar	298	55.76 ± 0.12	233.3 ± 0.5	[188]	1954

The vapor phase standard entropy of formation of H_2O_2 can be calculated from the Shomate equation:

$$S^\circ = A \ln(\tau) + B\tau + C\tau^2/2 + D\tau^3/3 - E/(2\tau^2) + G$$

where S is the entropy in $\text{J mol}^{-1} \text{ K}^{-1}$, A , B , C , D , E , and G are constants, and τ is the absolute temperature in K divided by 1000. The coefficients are listed in Table 28. Some of these coefficients (and others) were used earlier for a formula expressing the heat capacity or the enthalpy of formation of the vapor (Section 3.19.2.1). These equations were curve-fitted from data covering a range from 298 to 1500 K.

The structural, spectroscopic, and thermochemical properties of $\text{H}_2\text{O}_2(\text{G})$ were re-examined and recalculated, and revised ideal gas thermodynamic tables were published [330]. The revisions were based on new spectroscopic information and made use of improved calculational methods. Compared to previous calculations, the entropy at 298.15 K (Table 37) is unchanged for H_2O_2 , but the high-temperature values

Table 37: Ideal gas thermochemical properties of hydrogen peroxide H_2O_2 at standard state pressure and temperature.

$T, \text{ K}$	$C_p,$ $\text{J K}^{-1} \text{ mol}^{-1}$	$S^\circ,$ $\text{J K}^{-1} \text{ mol}^{-1}$	$[G^\circ - H^\circ(\text{Tr})]/T,$ $\text{J K}^{-1} \text{ mol}^{-1}$	$H^\circ - H^\circ(\text{Tr}),$ kJ mol^{-1}	$\Delta H_f^\circ,$ kJ mol^{-1}	$\Delta G_f^\circ,$ kJ mol^{-1}	$\log K_f$
298.15	42.416	234.542	234.542	0.000	-135.880	-105.681	18.515

Data source: [330]

($T > 4000\text{ K}$) are significantly different. The original publication contains tabulated data for up to 6000 K , which is, of course, useless because H_2O_2 will long have decomposed before it reaches that temperature.

3.19.7 Heat of Decomposition of Hydrogen Peroxide

The ability to decompose exothermically is one of the properties that makes hydrogen peroxide useful in steam generators for turbine drives and rocket engines.

The enthalpy of decomposition has been measured experimentally and can be calculated from tabulated data. The generally accepted enthalpy of decomposition in accordance with the equation

is $-98.70 \pm 0.08\text{ kJ/mol} = -23.59 \pm 0.02\text{ kcal/mol}$ and was derived from tabulated thermodynamic data. Experimental calorimetric determinations gave a value of $-98.07 \pm 0.12\text{ kJ/mol} = -23.44 \pm 0.03\text{ kcal/mol}$ [331]. Preliminary determinations of the heat of the reaction

catalyzed by Pt black at 273 K (0°C) and at various concentrations between 12.50 and 100% H_2O_2 in H_2O , gave $-98.49 \pm 0.17\text{ kJ/mol} = -23.54 \pm 0.04\text{ kcal/mol}$, a value slightly more exothermic than those found by previous authors [332].

For quick data lookup, although not very accurate, Figure 41 may suffice. The top line is for H_2O_2 going to liquid water and dioxygen, and the bottom line is for H_2O_2 going to steam and dioxygen. Note that by thermodynamic convention, the heat of decomposition is a negative number, but it is shown in Figure 41 as a positive number.

When we discuss enthalpy of decomposition of hydrogen peroxide, we usually think in terms of rocket engines operating on high concentrations of H_2O_2 and high temperatures. Only few of us realize that this reaction, catalyzed by enzymes, takes place continuously in our bodies, although fortunately with much lower H_2O_2 concentrations but with measurable heat output. The enthalpy of decomposition of hydrogen peroxide by catalase (EC 1.11.1.6) has been determined calorimetrically in isotonic saline solutions at 298 K (25°C) [293]. The value for the ΔH of decomposition for the reaction

was determined to be 100.4 kJ/mol ($24.0 \pm 0.3\text{ kcal/mol}$) at 298 K (25°C) in a closed reaction vessel.

When comparing the heat of decomposition as a function of H_2O_2 concentration, as the concentration of H_2O_2 in solution increases, there is less water to absorb the heat

Figure 41: Heat of decomposition of hydrogen peroxide. (Reproduced and modified from [7].)

of decomposition. The heat of decomposition increases, and the heat of evaporation decreases. A crossover occurs at 63–64% H₂O₂ where rapid, accelerated decomposition becomes self-sustaining, the decomposition generates dry steam, and the concentration of H₂O₂ in the residual decomposing solution can increase because water evaporates first.

3.20 Molecular Structure of Hydrogen Peroxide

Various aspects of the molecular structure of the hydrogen peroxide molecule have already been discussed in the section on spectra of hydrogen peroxide. Much of what we know about the molecular structure of H₂O₂ and its isotope analog has been derived from spectrographic measurements, sometimes supplemented by computational chemistry of this relatively simple molecule. Because hydrogen peroxide has a dipole moment and a very large dielectric constant, the molecule must be unsymmetrical. Of the three possible structures of H₂O₂

the structure with the O—O peroxide bond has been shown by molecular spectroscopy to be the correct structure. The unsymmetrical structure II has sometimes been called “water oxide”.

The molecular structure of hydrogen peroxide was the subject of avid debates among numerous early investigators for many years. Three possible structures have been suggested over the years. From dipole moment determinations on H_2O_2 in solution, Linton and Maass favored structure II, whereas Theilacker, arguing from dipole moment and parachor data, favored structure I. In 1934, Penney and Sutherland, based on quantum-mechanical calculations, proposed that structure III, in which the azimuthal angles (φ and θ) are both about 100° , should be more stable than either the *cis* or *trans* configuration ($\varphi = 0$ or 180°). Furthermore, this structure not only predicted a value of the dipole moment in good agreement with that determined by Linton and Maass, but it also correctly accounted for the Raman lines. Later theoretical work confirmed this configuration.

The O—O—H bond angle of unstrained oxygen bonds is usually 100° . This results in three possible conformations of the H—O—O—H molecule and eliminates a straight-chain, axisymmetrical planar molecule. Infrared spectra as a function of temperature reveal the thawing of the rotational degree of freedom around the O—O axis. As long as free rotation exists, the *cis* and *trans* isomers or the skewed form cannot be isolated as individual compounds. The minimum-energy configuration is the skewed chain molecule. This is similar to the hydrazine molecule, which can also exist in *cis* and *trans* configurations, but the least-energy state is in the skewed configuration. The energy of the molecule as a function of rotation around the O—O axis shows minima and maxima depending on the *cis*, *trans*, and skewed positions of the two H atoms. The dihedral (azimuthal) angle ϕ describing the angle between the two planes in which the H atoms are lying shows an energy minimum at 100° , the most likely skewed configuration. For a *cis* configuration, the angle would be 0° and for a *trans* configuration, the angle would be 180° . The O—O—H angle is of the order of 110° , like that of water. For water, the measured bond angle is 104.45° . The OH groups undergo either free rotation, hindered rotation, or torsional oscillation, depending upon the heights of the barrier of the hindering potential. Evidence of hindered rotation or torsional oscillation was found in the rotational fine structure of infrared spectra. Extensive investigations of the IR and Raman spectra of the H_2O_2 molecule have confirmed these configurations. Bond energies [333], force constants and moments of inertia have been calcu-

lated from these spectra. Similar calculations were performed to identify the weakest bonds in the molecule, the breakage of which is most likely to initiate a decomposition chain reaction.

The structural parameters of the H_2O_2 molecule are illustrated in Figure 42.

Figure 42: Structural parameters of the H_2O_2 molecule in comparison to H_2O
Distances in ångström = 10^{-10} m

It was stated above that the linear $\text{H}-\text{O}-\text{O}-\text{H}$ structure is the most likely structure for H_2O_2 . However, compounds with the unsymmetrical structure $\text{O}=\text{OH}_2$ (planar trigonal or pyramidal) have been claimed to exist as short-lived intermediates.

If it was not for the hydrogen bonding that connects H_2O_2 molecules in the condensed phase, H_2O_2 would have a boiling point like that of ethane. The high boiling point and high melting point of H_2O_2 and H_2O is the result of strong hydrogen bonding in the condensed phase. This is also expressed in the shift of IR absorption spectra when comparing spectra for the vapor and for the liquid. The Trouton constant for H_2O_2 is $111 \text{ J/mol} = 26.6 \text{ cal/mol}$, and it is similar to that of water ($109 \text{ J/mol} = 26.1 \text{ cal/mol}$), typical for associated liquids. Theoretically, for non-associated liquids, the Trouton constant should be $87.8 \text{ J/mol} = 21 \text{ cal/mol}$.

In reviewing the literature on the physical properties of hydrogen peroxide, one inevitably stumbles across many references to the deuterium isotopomer D_2O_2 and the hybrid HDO_2 . These compounds are not used as rocket propellants, and we would not mention them here if it was not for their utility in explaining the unique properties of H_2O_2 by comparing spectra and electronic properties. The substitution of H with D changes the natural frequencies and absorption characteristics of bond vibrations and helps the spectroscopist in the assignment of the absorption bands to certain parts of the molecule. The same applies to any other molecule in which hydrogen has been replaced with deuterium, but the $\text{H}_2\text{O}_2/\text{D}_2\text{O}_2$ system has been exceptionally well studied. The isotope effect is most distinct in low-molecular mass molecules such as H_2O , H_2O_2 , or NH_3 . D_2O_2 forms and accumulates as an unwanted byproduct in heavy-water cooled nuclear reactors.

Another type of nuclear reactor carries the fissionable uranium not in metallic or oxide form as a solid but dissolved in an aqueous solution, which becomes critical only as it circulates through the core of the radiation-shielded neutron source. In this solution, hydrogen peroxide (or deuterium peroxide, depending on the solvent) forms and decomposes with unequal speed, potentially leading to accumulation of H_2O_2 or D_2O_2 in the circulating water and altering its corrosive behavior [334].

Collisional activation, charge reversal, and six different neutralization-reionization mass spectrometric experiments with $[\text{H}_2\text{O}_2]^+$ radical cations and $[\text{H}_2\text{O}_2]^-$ radical anions were performed in order to probe the often disputed existence of neutral water oxide, $\text{H}_2\text{O}=\text{O}$, the long sought after tautomer of hydrogen peroxide, HOOH in the unsymmetrical structure II that has sometimes also been called “water oxide” [335]. Experiments together with *ab-initio* calculations indicated that $\text{H}_2\text{O}=\text{O}$ is a local minimum on the $[\text{H}_2\text{O}_2]$ potential-energy surface, and the elusive molecule seems to be formed as a transient upon neutralization of the corresponding radical cation H_2OO^+ in the gas phase. Even if it could be stabilized, it is doubtful that it would be a better rocket propellant than $\text{H}-\text{O}-\text{O}-\text{H}$; see also [336].

3.20.1 Rotational Barrier Energies in Hydrogen Peroxide

The infrared spectra of H_2O_2 are characterized by the band splitting caused by an internal rotation barrier along the axis of the $\text{O}-\text{O}$ bond. There is a vast amount of literature that deals with the energetics of internal rotation and their effect on the spectral and thermodynamic properties of this molecule. We have tabulated some of this literature in Table 38 because it is closely related to the energetics of H_2O_2 decomposition. Internal rotation can take place only as long as the $\text{O}-\text{O}$ bond is strong enough to hold the molecule together. Rotational barrier measurements and calculations are important to assess the stability of the hydrogen peroxide molecule and to determine the threshold where the molecule begins to decompose once internal vibrations and rotations become so vigorous that the chemical bonds can no longer hold the molecule together. For this reason, this chapter, although highly theoretical, is included in a book on rocket propellants.

There are many other dumbbell-shaped molecules where the two halves of the molecule rotate around the connecting axis, with or without rotational barriers. Hydrogen peroxide has frequently been compared to these other molecules, including ethane C_2H_6 , hydrazine N_2H_4 , disulfane H_2S_2 , and some containing more than two different atoms, such as methanol CH_3OH , hydroxylamine NH_2OH , and methylamine CH_3NH_2 . The publications listed in Table 38 are also useful in determining rotational barriers and energy levels in these other molecules; many of those are also used as rocket propellants. This information helps us to understand the peculiar properties of the hydrogen peroxide molecule that make it so attractive as a rocket propellant.

3.20.2 Computational Methods for Characterization of the Hydrogen Peroxide Molecule

The hydrogen peroxide molecule has unique properties that give it a high energy content that makes it suitable as a rocket propellant. While many parameters needed for the evaluation of H_2O_2 as a rocket propellant need to be determined experimentally, there has been a substantial effort to predict those parameters from theoretical calculations. Hydrogen peroxide is a relatively simple molecule, and many computational

chemists have used it as a benchmark to test the accuracy of their calculation methods and molecular models. This type of computational chemistry is useful to explain physical properties of existing molecules, and it is also useful in predicting physical properties of theorized, even more energetic molecules that so far exist only on paper and are waiting to be discovered. Similar calculations have been performed for many other rocket propellants. In the case of hydrogen peroxide, a relatively simple molecule, these calculations were relatively easy but challenging due to the ability of the two halves of the molecule to rotate or oscillate around the O—O axis of the molecule. Often, these calculations were performed side-by-side with actual spectral measurements and were often cited as a confirmation and proof of the correctness and accuracy of assumptions about energy levels in the molecule. One objective of these theoretical calculations is to determine the threshold of energy at which the molecule begins to break apart, starting an exothermic reaction. It is this exothermic reaction that enables hydrogen peroxide and other energetic molecules to act as monopropellants. This computational method can be applied to hydrogen peroxide and other dumbbell-shaped molecules like hydrazine or hydroxylamine [337].

The electronic structure of the hydrogen peroxide molecule in three different configurations, namely the *cis*, the *trans*, and the non-planar or skew forms, were calculated using Linear Combination of Atomic Orbitals (LCAO)-Molecular Orbital (MO)-Self-Consistent Field (SCF) approximations [338]. All the electrons were considered except those of the K-shell of the oxygen atoms. The orbitals of these atoms are essentially of the sp^3 hybrid type. It was shown that the skew form of the molecule with an azimuthal angle Φ of about 120° is the most stable, due mainly to conjugation of the σ_5 and σ_6 orbitals of the oxygen atoms with the other molecular orbitals. On the contrary, in the *cis* and *trans* forms these two orbitals are non-bonding. The predictions were compared to measured values of the ionization potentials, and the dipole moment and the predicted dipole moment, 2.05 D, agreed well with the experimental data.

A similar study of the electronic structure of the hydrogen peroxide molecule by a LCAO-SCF quantum chemical method gave a dipole moment of 2.71 D [339].

Equilibrium structure and barriers to internal rotation of hydrogen peroxide were accurately determined with a Hartree-Fock (HF) method and Rayleigh-Schroedinger perturbation theory [340]. The computed bond lengths [$R(\text{OO}) = 1.451 \text{ \AA}$, $R(\text{OH}) = 0.967 \text{ \AA}$] and angles [$\angle(\text{OOH}) = 99.3^\circ$ and $\angle(\text{HOOH}) = 119.3^\circ$] were in good agreement with experiment while near HF values lead to a false structure [$R(\text{OO}) = 1.390 \text{ \AA}$, $R(\text{OH}) = 0.943 \text{ \AA}$, $\angle(\text{OOH}) = 102.9^\circ$, $\angle(\text{HOOH}) = 111.2^\circ$].

Infrared intensities for the fundamental vibrations of H_2O_2 were predicted using atomic polar tensors obtained from *ab-initio* quantum mechanical calculations employing a 4-31G basis set [341]. The absolute intensities calculated quantum mechanically for H_2O_2 were compared to the previously reported intensities for H_2O_2 obtained by transferring a hydrogen atomic polar tensor to H_2O_2 from H_2O . These comparisons enabled estimates to be made for the infrared intensities of H_2O_2 as

follows: $A_1 = 14.5$ km/mol, $A_2 = 0.91$ km/mol, $A_3 = 0.058$ km/mol, $A_4 = 123$ km/mol, $A_5 = 46.2$ km/mol, and $A_6 = 101$ km/mol.

A series of *ab-initio* calculations of the internal structure of the HOOH molecule give us a better understanding of the forces that hold the molecule together and the energy levels it goes through as it rotates, oscillates, gets excited, and, eventually, breaks apart, releasing energy that can be used for rocket propulsion. Calculation of the oscillator strengths and optical rotatory strengths are part of this process [342]. Such *ab-initio* calculations can also be combined with traditional density-functional theory (DFT) methods. Comparison with experimental data and also with results from *ab-initio* methods (HF and correlated levels) showed a good performance of non-local density functional methods for the description of the hydrogen peroxide geometry, especially the torsion angle τ , when basis sets of sufficient quality were used. Different density functionals were then used in order to study *cis* and *trans* rotational transition states [343].

The potential energy surfaces for the singlet and triplet H_2O_2 molecular system were studied by using various methods suitable for examining most of the species and reaction paths on the H_2O_2 potential energy surfaces [344]. The hydrogen abstraction reaction $\text{O} + \text{H}_2\text{O} \rightarrow \cdot\text{OH} + \cdot\text{OH}$ has a small or no energy barrier, suggesting this pathway may have relevance to the astrochemical formation of hydrogen peroxide in extraterrestrial environments.

The argument about the possible existence of a structural isomer of H_2O_2 has received new ammunition with the completion of *ab-initio* calculations [345]. *Ab-initio* molecular electronic structure theory was applied in an investigation of the oxywater-hydrogen peroxide isomerization. Oxywater, hydrogen peroxide, and the transition state connecting them have been located using a self-consistent-field configuration interaction including all single and double excitations and coupled cluster with single and double excitations methods with several basis sets. A classical barrier to isomerization of 5.7 kcal/mol has been predicted at the highest level of theory. Although these *ab-initio* predictions could be decreased by 1 or 2 kcal/mol, it was suggested that there can be little doubt that oxywater is a genuine minimum of the H_2O_2 potential energy hypersurface; see also [346–352].

The relative intensities of absorption bands of H_2O_2 in the far IR region can be calculated using a weak coupling of the vibrational, torsional, and rotational motions [353]. The contribution to the absorption band intensities due to a change of the rotational state of the molecule can be calculated using the 3j-symbols technique.

Highly accurate *ab-initio* variational calculations of the rotation-vibration energy levels of H_2O_2 in its electronic ground state used a recently computed potential energy surface and the variational nuclear-motion programs WARV4, which uses an exact kinetic energy (EKE) operator, and Trove, which uses a numerical expansion for the kinetic energy [354]. The Trove calculations were performed for levels with high values of rotational excitation, J up to 35. The calculations of the rovibrational energy levels reproduced the observed levels with a standard deviation of about 1 cm, simi-

lar to that of the $J = 0$ calculation as the discrepancy between theory and experiment for rotational energies within a given vibrational state is substantially determined by the error in the vibrational band origin. Minor adjustments were made to the *ab-initio* equilibrium geometry and to the height of the torsional barrier. Using these data and correcting the band origins using the error in $J = 0$ states lowers the standard deviation of the observed calculated energies to only 0.002 cm for levels up to $J = 10$ and 0.02 cm for all experimentally known energy levels, which extended up to $J = 35$.

3.20.3 Dimer and Polymer Association in the Vapor Phase

Hydrogen peroxide, like water, is strongly associated in the liquid phase through hydrogen bonds, allowing it to exist as a liquid at room temperature. Experimental vapor density measurements at 365 K ($92^\circ\text{C} = 165.6^\circ\text{F}$) showed that H_2O_2 is not associated in the vapor state [210].

The experimental investigation of the temperature dependence of the degree of association of pure liquids, water and hydrogen peroxide in the vapor phase has been supported by theoretical investigations in this direction. The possibility of using various methods for calculating the entropy of vapor formation of non-associated liquids, like water and hydrogen peroxide has been considered [355], including the use of the Hildebrand rule as made more rigid by Pitzer. The latter method does not however, lead to any improvement in the results since it is necessary to use values for the volume of the associated liquid, which inevitably introduces errors into the calculation. The results of calculating the temperature dependence of the monomer content was in good agreement with literature data of over the entire temperature range.

In the vapor above hydrogen peroxide/water mixtures, the two molecules form clusters of two or more molecules. High levels of *ab-initio* MO theory were used to calculate the structures, binding energies, vibrational frequencies and equilibrium constants of hydrogen peroxide-water dimers in the vapor phase [356]. The geometries of the different possible conformers were optimized and five different stationary points on the potential-energy surface were characterized, but only two were minima. The global minimum corresponded to a five-membered ring, where both monomers behave simultaneously as proton donors and proton acceptors. In the second minimum, which was about $9.2\text{ kJ/mol} = 2.2\text{ kcal/mol}$ higher, the hydrogen peroxide monomer behaved as a proton acceptor, while water behaves as a proton donor.

The same method was used to calculate the structures, binding energies, vibrational frequencies and equilibrium constants of hydrogen peroxide dimers in the absence of water [357]. Five different stationary points were found at this level, but only two of them were minima. The geometries of these two minima were refined, and their vibrational frequencies showed a sizeable red shift of the stretching vibrations of the proton donors. The global minimum corresponded to a six-membered ring having C_i symmetry; whereas, the second minimum is a five-membered ring, which lies about

1.1 kcal/mol above the global one. The formation of the latter implies a considerable enhancement of the dipole moment.

Hydrogen peroxide molecular clusters tend to form hydrogen-bonded cyclic and cage structures along the lines expected of a molecule, which can act as a proton donor as well as an acceptor. Results of density functional theory (DFT) and HF calculations suggest the formation of stable helical structures for larger clusters [358].

3.20.4 Molecular Structure of Frozen Hydrogen Peroxide

Hydrogen peroxide crystallizes into a tetragonal structure of $\text{H}_2\text{O}_2(\text{I})$, space group $D_4^4 - P4_12_12$ with four molecules in the unit cell, at -0.41°C and ambient pressure. The unit cell parameters were found to be $a = 4.06 \text{ \AA}$, $c = 8.00 \text{ \AA}$ at 253 K from single crystal XRD studies [359]. The observed density was 1.71 g/cm^3 at 253 K. Each oxygen atom has two close approach distances of $2.78 \text{ \AA}$ and two longer ones of $2.90 \text{ \AA}$, resulting in a very compact crystal. The nature of the hydrogen bonds formed in this crystal are also of interest, both in view of the unusually high density (1.70 g/cm^3) and in comparison to those formed in water ice, where the distance is given as $2.76 \text{ \AA}$.

Neutron studies revealed more information about the molecular structure of H_2O_2 : The O—O bond distance $d(\text{O—O})$ is $1.453 \pm 0.007 \text{ \AA}$ and $d(\text{O—H})$ is $1.008 \pm 0.005 \text{ \AA}$ (after correction for the thermal motion) [360]. The O—O—H and dihedral angles are $102.7 \pm 0.3^\circ$ and $90.2 \pm 0.6^\circ$, respectively. An infinite helix is formed through the network of O—O bonds around the fourfold screw axes along the c-axis.

The dihedral motion, O—H rotational with respect to O—O in H_2O_2 , has a very small energy barrier, 2.5 kcal/mol , resulting in high flexibility of H_2O_2 molecules.

If liquid H_2O_2 is subjected to very high pressures in a diamond anvil cell, it freezes at 1.5 GPa and ambient temperature into a tetragonal structure $P4_12_12$, $Z = 4$, denoted as $\text{H}_2\text{O}_2\text{-I}$ [361]. This is the same transition that has previously been reported in this material at 253 K. The unit cell parameters at 6.3 GPa are $a = 3.759 \text{ \AA}$, $c = 7.397 \text{ \AA}$, and $V = 15.74 \text{ cm}^3/\text{mol}$, representing 21% compression from that at ambient pressure. $\text{H}_2\text{O}_2\text{-I}$ has been found to transform into a high-pressure phase $\text{H}_2\text{O}_2\text{-II}$ at 7.5 GPa. One of most interesting results from this study was the discovery of the phase transition from tetragonal $\text{H}_2\text{O}_2\text{-I}$ to $\text{H}_2\text{O}_2\text{-II}$ near 7.5 GPa. The crystal structure of $\text{H}_2\text{O}_2\text{-II}$ appears to be an orthorhombic structure $Pmmn$. The infinite helix formed around the fourfold screw axis in $\text{H}_2\text{O}_2\text{-I}$ is deformed by possible partial disordering of the proton. The information suggested that $\text{H}_2\text{O}_2\text{-II}$ is denser and has stronger hydrogen bonds than $\text{H}_2\text{O}_2\text{-I}$. Both $\text{H}_2\text{O}_2\text{-I}$ and $\text{H}_2\text{O}_2\text{-II}$ were found to be stable chemically at high pressures, but they decompose into oxygen and H_2O at the onset of melting. The high stability of H_2O_2 at high pressure is probably due to a large kinetic barrier associated with decomposition.

3.21 Electron Impact Ionization and Mass Spectrometry of Hydrogen Peroxide

An investigation was made to determine the conditions of the reactions of hydroperoxyl and hydroxyl radicals and oxygen atoms in the presence of hydrogen peroxide [362]. For detection by positive ion beam mass spectroscopy, the radicals must be ionized to HO_2^+ and OH^+ by collision with electrons. The same ions are produced by dissociation of hydrogen peroxide induced by collision with electrons having an energy greater than the appropriate appearance potential. The appearance potentials of the ions HO_2^+ , OH^+ , and O^+ formed by dissociation of H_2O_2 were therefore investigated and are listed in Table 39.

Table 39: Appearance potentials of hydrogen peroxide ions or fragments in mass spectrometry

Ion or fragment	Appearance potential, eV
H_2O_2^+	12.1 ± 0.3
HO_2^+	16.1 ± 0.4
OH^+	16.0 ± 0.3
O^+	$>18.9 \pm 0.4$

Previous estimates of 13.6 eV for the ionization potential of the hydroxyl radical were confirmed. The ionization potential of hydrogen peroxide is 12.1 ± 0.3 eV. The minimum heat evolved in the formation of HO_2 from H and O_2 is equal to the ionization potential of HO_2 , which is 235 ± 9 kcal or 46 kcal assuming $I(\text{HO}_2) = 12.2$ eV. The appearance potential of OH^+ from H_2O_2 is less than that from H_2O (18.7 eV). For HO_2^+ , the observed appearance potential of 16.1 eV then equals the sum of the ionization potential of HO_2 , the H—OOH bond dissociation energy, and any kinetic or excitational energy of the dissociation products.

The appearance potentials of H_2O_2 electron bombardment fragments were determined from a plot of the logarithm of the ion current versus the electron accelerating voltage [363]. The peak intensities were corrected based on the assumptions that H_2O_2 does not make a 32 peak (O_2^+), and that there is not a rearrangement peak at mass 18 (H_2O^+). The dissociation energy for the O—O bond was found from the equation:

$$A(\text{OH}^+) = D(\text{HO—OH}) + I(\text{OH})$$

where A = appearance potential, D = dissociation energy, and I = ionization potential of the species indicated in parentheses. Assuming $D(\text{H—OH}) = 5.06$ eV gives $D(\text{HO—OH}) = 200 \text{ kJ} = 47.8 \pm 3 \text{ kcal}$, which is in fair agreement with $217 \text{ kJ} = 52 \text{ kcal}$ obtained from thermochemical measurements.

Several reactions have the ability to produce HO_2 radicals: **(1)** reaction of H with O_2 , **(2)** reaction of H with H_2O_2 , **(3)** reaction of O with H_2O_2 , **(4)** reaction of OH with H_2O_2 , **(5)** photolysis of H_2O_2 , and **(6)** low-power electrical discharge in H_2O_2 . Mass

spectrometric analysis for the purpose of identification and determination of thermochemical energies of HO_2 showed that the low-power electrical discharge in H_2O_2 provided the most intense and convenient source of HO_2 radicals [364].

The measured values are: ionization potential of HO_2 , $I(\text{HO}_2) = 11.53 \pm 0.02 \text{ eV}$, and appearance potential $A(\text{HO}_2^+) = 15.36 \pm 0.05 \text{ eV}$ with an estimated absolute accuracy of $\pm 0.1 \text{ eV}$. The derived bond dissociation energies D thermochemical energies are: $D_0(\text{H}-\text{OOH}) = 370 \text{ kJ/mol} = 88.4 \pm 2 \text{ kcal/mol}$, $D_0(\text{H}-\text{O}_2) = 192 \text{ kJ/mol} = 45.9 \pm 2 \text{ kcal/mol}$, $\Delta H^\circ_{\text{OOH}}(\text{HO}_2) = 23.8 \text{ kJ/mol} = 5.7 \pm 2 \text{ kcal/mol}$ for the values at 0 K; and $D(\text{H}-\text{OOH}) = 374.9 \pm 8.4 \text{ kJ/mol} = 89.6 \pm 2 \text{ kcal/mol}$, $D(\text{H}-\text{O}_2) = 197.1 \pm 8.4 \text{ kJ/mol} = 47.1 \pm 2 \text{ kcal/mol}$, and $\Delta H^\circ_{298}(\text{H}-\text{O}_2) = 20.9 \pm 8.4 \text{ kJ/mol} = 5.0 \pm 2 \text{ kcal/mol}$ for the corresponding values at 298 K (25°C). Ion-molecule reactions, which are negligible in normal operation of mass spectrometers, were shown to be a potentially serious source of interference in studies of HO_2 with conventional mass spectrometers.

4 Chemical Properties of Hydrogen Peroxide

The most pronounced chemical properties of hydrogen peroxide are its thermal instability and its oxidizing capability. In many chemical reactions in the analytical laboratory and in the chemical process industry, hydrogen peroxide is preferred as a clean oxidizer because it does not leave any residues. One must keep in mind, however, that towards very strong oxidizers (such as potassium permanganate) hydrogen peroxide acts as a reducing agent, and it is converted to elemental dioxygen.

When dozens of drums of concentrated hydrogen peroxide that were impounded by the victorious Allied Forces at the end of WWII in Germany were shipped across the Atlantic to the United States for further analysis and to support the post-war launches of A-4 (V-2) rockets under the supervision of the US Army, the drums brought with them the dubious reputation of containing an unstable chemical that had caused many drums to explode unexpectedly. Those reports were mostly based on happenings at the mobile V-1 launch sites during WW-II, where the pistons in catapults that launched the air-breathing “buzz-bomb” cruise missiles were powered by a steam generator fed with coinjected hydrogen peroxide and calcium permanganate solutions.

Several publications dealing with hydrogen peroxide in the years from 1946 to 1949 reflect the effort of the US chemical industry to come up to speed in making, storing, selling, and shipping this energetic chemical [365–367]. These publications are now only of historical interest.

4.1 Miscibility, Solubility, and Solvent Properties of Hydrogen Peroxide

4.1.1 Miscibility

Hydrogen peroxide is a hydrophilic, polar, protic solvent and is miscible with all other protic solvents. It dissolves in aprotic solvents such as diethyl ether to a greater extent than water.

Hydrogen peroxide is miscible in all proportions with water, methanol, ethanol, isopropanol, ethyl cellosolve, acetone, or pyridine. One must remember, however, that most mixtures of concentrated hydrogen peroxide with organic compounds are potentially detonable and many will even autoignite on standing or on contact. The miscibility of hydrogen peroxide with other organic liquids is generally greater (wider) than that of water.

In addition, hydrogen peroxide is more soluble than water in several organic liquids. Table 40 lists the number of grams of 90% hydrogen peroxide that will dissolve in 100 grams of the listed solvents at room temperature [367]. The corresponding numbers for water are listed for comparison. Looking at mixtures of hydrogen peroxide with organic solvents, one must remember that all these mixtures are potentially detonable (*Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide”). In spite of this hazard, mixtures of hydrogen peroxide with alcohols have been tested as rocket propellants, sometimes with catastrophic results.

Table 40: Miscibility of hydrogen peroxide with organic solvents.

Organic solvent	g of 90% H ₂ O ₂ per 100 g of solvent	g of water per 100 g of solvent
Dimethyl phthalate	28	1.6
Diethyl phthalate	2.5	1.0
Ethyl acetate	4	3.5
Aniline	4	3.5

Data source: [367]

Ammonia gas will dissolve in hydrogen peroxide similarly to how it will dissolve in water, but there is concern that such solutions will decompose or explode spontaneously. If the solutions were stable enough, they would make a good monopropellant. Maybe it must be kept cold all the time.

At temperatures below 243 K (−30 °C) and with more than 30% H₂O₂, hydrogen peroxide forms stable solutions in liquid ammonia. In liquid ammonia as a solvent, H₂O₂ behaves like a weak acid. Reactions of H₂O₂ with sodium amide or sodium metal dissolved in liquid ammonia lead to formation of sodium peroxide, which is not soluble

in liquid ammonia [368]:

In solutions of ammonium nitrate NH_4NO_3 in liquid ammonia, the AN would act as a Bronsted acid and when reacted with a suspension of finely ground Na_2O_2 , anhydrous H_2O_2 can be generated and separated from the excess ammonia solvent and the NaNO_3 residue by fractionated distillation:

It was suggested that this might be a method to make anhydrous H_2O_2 starting with less concentrated H_2O_2 . It is an omission that this publication ignores the formation of a $\text{H}_2\text{O}_2 \bullet \text{NH}_3$ adduct like NH_4OH .

4.1.2 Hydrogen Peroxide as a Solvent for Solid Compounds

Hydrogen peroxide is a polar solvent, and many salts and other neutral solid compounds are soluble in hydrogen peroxide (as long as they do not react with it or destabilize it).

It was common practice to dissolve potassium hydroxide in hydrogen peroxide solutions in order to use this solution as a working fluid in chemical lasers Airborne Laser – Chemical Oxygen Iodine Laser (ABL-COIL) for making atomic oxygen. It was known that H_2O_2 is less stable in alkaline than in acidic solutions, but it was thought that the material was safe to store. This casual attitude changed when a large tank with basic hydrogen peroxide exploded (Section 7.8). The physical properties of basic hydrogen peroxide solutions had been summarized [369], but the safety properties were lacking. New methods developed for preparing mixed-base hydrogen peroxide for use in the ABL-COIL include mixing and simultaneously cooling the mixture with liquid nitrogen [370]. The temperature had to be maintained below 280 K (7°C). Dissolving the alkali metal hydroxides in hydrogen peroxide solutions is a very exothermic process. About 50 kJ (12 kcal) of heat are released per mol base added. Instead of KOH, mixtures of KOH, NaOH and LiOH can be used. Typically, the molar ratio of $[\text{H}_2\text{O}_2]$ to $[\text{OH}]$ was about 1.15.

Solid oxidizers like ammonium nitrate or ammonium dinitramide are readily soluble in hydrogen peroxide, and such solutions have been evaluated as oxidizers that have a lower freezing point and higher density than plain hydrogen peroxide. Instead of dissolving AN in water, a more powerful oxidizer called PERSOL-1 can be obtained by dissolving AN in hydrogen peroxide/water mixtures [198, 371]. PERSOL-1 contains 55.6% AN, 22.2% H_2O_2 , and 22.2% H_2O . This blend freezes at 276 K (+3°C) and has a density of 1.361 g/cm³. The freezing point diagram of the

ternary system AN/H₂O₂/H₂O will be shown in *Encyclopedia of Oxidizers*, chapter “Nitrate Oxidizers”. Many of these solutions do not have sharp freezing points but instead have glass transition points. The ignition delays of solutions of AN or ADN in HTP with an ionic liquid fuel, 1-allyl-3-methylimidazolium dicyanamide, were measured [372].

4.2 Autodissociation Constant of Hydrogen Peroxide

The acid constant of the reaction

is 1.78×10^{-12} at 293 K (20 °C). The $\text{p}K_{\text{a}}$ is 11.75. Other sources give $\text{p}K_{\text{a}}$ as 11.65 ± 0.10 . The heat of dissociation is 34.3 kJ/mol = 8.2 kcal/mol. As a weak acid, hydrogen peroxide forms salts with various metals, which usually hydrolyze when dissolved in water. Hydrogen peroxide is a much weaker base than water, but it can still form adducts with very strong acids. The strong superacid HF/SbF₅ forms unstable salts containing the H₃O₂⁺ ion.

There are two types of dissociation constants for hydrogen peroxide: those in aqueous solution and those of dissociation in the vapor phase. The one in aqueous solution goes to ionic species and is reversible, and dissociation in the gas phase often goes to free radical species as intermediate fragments of the irreversible decomposition process.

In the reaction

the equilibrium lies over on the right because H₂O₂ is a weaker base and a stronger acid than H₂O. The reaction enthalpy of this proton exchange is $\Delta H = -17.57 \pm 5.02$ kJ/mol = -4.2 ± 1.2 kcal/mol [373]. The $\text{p}K_{\text{a}}$ value of H₂O₂ dissociation is 11.75 ± 0.02 , which corresponds to a dissociation constant of $1.78 \pm 0.1 \times 10^{-12}$ at 20 °C. The enthalpy of reaction ΔH is 34.3 kJ/mol = 8.2 kcal/mol, the entropy of reaction ΔS is 107.5 J mol⁻¹ K⁻¹ = 25.7 cal mol⁻¹ °C⁻¹, and the free energy ΔG of the reaction is 66.1 kJ/mol = 15.8 kcal/mol.

Glass electrodes can give accurate pH measurements even in non-aqueous solvents like hydrogen peroxide. The standard potential of glass electrodes in H₂O/H₂O₂ mixtures was measured over the entire range of compositions [374]. Thus, if the dissociation of a weak acid and the pH of a solution of its sodium salt in a solvent mixture are known, the ionic product of the solvent can be calculated directly from the equation:

$$\text{p}K'_{\text{M}} = 2\text{pH} - \text{p}K'_{\text{A}} - \log c_{\text{A}^-}$$

where $\text{p}K'_{\text{M}}$ is the negative logarithm of the ionic product of the solvent medium, pH is the pH of the solution of the sodium salt, $\text{p}K'_{\text{A}}$ is the negative logarithm of the dissoci-

ation constant of the acid, and c_{A^-} is the concentration of the anions from the sodium salt of the acid. The ionization constants of H_2O/H_2O_2 mixtures were measured by titration of sodium hydroxide or piperidine with perchloric acid in the mixed solvents and measuring the pH at the equivalence point. The pK of the solvent is twice the value of the pH at the equivalence point. The pK_a as a function of the H_2O_2 content of the solvent goes through a minimum [375].

Autodissociation of hydrogen peroxide in aqueous solution results in formation of H^+ and HOO^- ions:

The equilibrium constant

$$K = [H^+][HOO^-]/[HOOH]$$

is 2.4×10^{-12} at room temperature. Hydrogen peroxide is a stronger “acid” than water. The pH of a 90% aqueous solution is near 4.9 (even in the absence of phosphoric acid, which is sometimes added as a stabilizer). In spite of the more acidic pH, the corrosive action of H_2O_2 is only moderate, but the materials of construction must be selected very carefully (Section 5). Alkali metal peroxides will hydrolyze in water and release hydrogen peroxide and form a solution of alkali metal hydroxide in water. Such alkaline solutions of hydrogen peroxide are not very stable.

Upon dilution with conductivity quality pure water, the pH of several H_2O_2 samples from different sources increased from 0 to 5 when the samples were diluted from 90 to 10% H_2O_2 [376].

4.3 Adduct and Compound Formation in Aqueous Solutions

Hydrogen peroxide can form several adducts and compounds in aqueous solutions. Some of these may be of interest as rocket propellants. One must be careful when mixing an oxidizer like hydrogen peroxide with a fuel like ammonia. The potential explosive hazard of such mixtures is unexplored.

Dry ammonia was passed into anhydrous hydrogen peroxide kept at 273 K (0 °C). The gas dissolved readily and, after a considerable amount had gone into solution, white crystals formed. These were filtered off and dried with filter paper; analysis showed that they had a composition corresponding to $NH_3 \cdot H_2O_2$ [312].

Thermal analysis of the system NH_3 - H_2O_2 - H_2O showed the existence of two compounds: $NH_3 \cdot 3H_2O_2 \cdot 6H_2O$ with a melting point of 244.3 K (−28.8 °C) and another with a melting point of 258 K (−15 °C), which is probably $(NH_4)_2O_2 \cdot 2H_2O$ [377]. Two eutectic points were observed at 218.65 K (−54.5 °C) (0.7% NH_3) and 239.75 K (−33.4 °C) (12.5% NH_3).

A compound called *ammonium hydroperoxide* may have formed when thin films were successively condensed from the vapors of H_2O_2 and NH_3 on NaCl plates at

93.1 K (−180 °C) [378]. A reaction took place between the solids when the temperature was allowed to rise to 195 K (−78 °C). The IR spectrum showed the 1630-cm^{−1} and 1450-cm^{−1} bands of the NH₄⁺ ion and the O—O stretching band at 836 cm^{−1}. A new band at 1100 cm^{−1} was attributed to a bending mode of the O₂H[−] ion.

It was found that the peroxide remained stable and the ammonia unoxidized when in contact at low temperatures, that is, below 273 K (0 °C). A saturated solution of gaseous ammonia in 99.5% H₂O₂ was allowed to warm to room temperature, but when it was agitated, the solution exploded [379].

4.4 Reactions of Hydrogen Peroxide

For rocket propulsion applications, the most important reactions of hydrogen peroxide are the monopropellant catalytic decomposition reactions and the autoignition with a few select fuels in hypergolic bipropellant combinations. Technical applications of catalytic decomposition reactions will be discussed in *Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide”, regardless of whether they involve academic studies in the laboratory or actual flight hardware. The effects of inadvertent contaminants on the slow decomposition of H₂O₂ are discussed in Section 4.5.5 on storability.

4.4.1 Redox Reactions of Hydrogen Peroxide

Hydrogen peroxide is unusual in that it can be both an oxidant and a reducing agent, depending on the nature of the compounds it is reacting with.

A very unusual phenomenon was observed during reactions of hydrogen peroxide with chromate in a weakly acidic medium at elevated temperature and at high initial concentration of hydrogen peroxide. Oscillatory periodic changes of pH occurred during the chromate-catalyzed decomposition of hydrogen peroxide in a weakly acidic medium at elevated temperature and at high initial concentration of hydrogen peroxide [380]. In a closed system, there were only two or three periods, but sustained oscillation occurred in a continuous stirred tank reactor (CSTR). In closed systems, the oscillating temperature exhibited a maximum (up to 15 °C increase), but in a CSTR, sustained oscillation occurred at a constant stationary temperature.

4.4.1.1 Reactions of Hydrogen Peroxide with Iron Ions

Iron ions are ubiquitous and may be leached from steel vessels or steel components (valves, fittings) that the liquid comes into contact with. Iron contamination accelerates the decomposition of H₂O₂ during storage. Reactions of H₂O₂ with Fe²⁺ or Fe³⁺ ions result in a series of reactions that have been examined very thoroughly because they generate free •OH radicals as an intermediate (Fenton reagent). Such free radicals can serve as initiators for free radical chain reactions such as polymerizations,

calibration of an electron spin resonance (ESR) instrument, and in a biologic system of living cells, they may induce cancer. They are also effective in destroying organic contaminants in industrial waste streams.

The reaction of Fe^{3+} with H_2O_2 proceeds via the following three initial steps [381]:

which occur after the preequilibrium

At 298 K (25°C) and ionic strength 0.45, the rate constant (k) of the first reaction is $1.6 \times 10^{-3} \text{ L mol}^{-1} \text{ s}^{-1}$, and the activation energy (E_a) is $92 \text{ kJ/mol} = 22 \text{ kcal/mol}$; the rate constant for the second reaction is $k = 5.0 \text{ L mol}^{-1} \text{ s}^{-1}$, $E_a = 50 \text{ kJ/mol} = 12 \text{ kcal/mol}$, and the rate constant for the third reaction is $k = 2 \times 10^{-4} \text{ L mol}^{-1} \text{ s}^{-1}$. When these rate constants and the proposed (ion-free radical) mechanism were applied to published data, they agreed well with the experimental values. A rate law of the catalytic decomposition of H_2O_2 was derived that at $[\text{Fe}^{3+}] : [\text{H}_2\text{O}_2]$ ratios of equal to or greater than 1 follows the equation

$$-d[\text{H}_2\text{O}_2]/dt \approx [\text{Fe}^{3+}][\text{H}_2\text{O}_2]^{1.5}/([\text{H}^+] + K)$$

where K is the equilibrium constant for

Peroxy complexes where H_2O_2 is temporarily included in the sphere of hydration of the iron(III) ion are intermediates in the iron-catalyzed decomposition of H_2O_2 [382, 383]. Similar peroxy complex intermediates are formed in the reactions of H_2O_2 with chromate [384, 385] or molybdate ions [386, 387].

Here, we are mostly interested in reactions of H_2O_2 with iron compounds as an unwanted reaction leading to accelerated decomposition of HTP during storage if it becomes contaminated by iron leached from the wall of storage containers or flow system components (plumbing, valves, pumps, filters). We are also interested in catalytic iron compounds (dissolved iron compounds in a solvent) that can be squirted into a decomposition chamber as a liquid catalyst simultaneously with H_2O_2 , causing instant controlled decomposition and initiation of combustion where H_2O_2 is used as an oxidizer in bipropellant rocket engines.

4.4.2 Reaction Mechanisms of H_2O_2 Reactions with Other Inorganic Species

Hydrogen peroxide can react with many other compounds. The reactions of prime interest are those that promote instant decomposition or lead to hypergolic ignition of

two (or more) reactants, as will be discussed in more detail in a later volume of this series where we deal with bipropellants.

Attempts to synthesize a higher peroxide by reaction of H_2O_2 with ozone instead resulted in decomposition of ozone and H_2O_2 acting as a reducing medium:

This is a reaction proceeding via free radical intermediates. Attempts to identify semistable associate complexes in the O_3 and H_2O_2 system by computational chemistry using time-dependent density functional theory found four complexes as semistable structures of $\text{O}_3\text{-H}_2\text{O}_2$ [388]. Natural bond orbital analysis and quantum theory of atoms in molecules were employed to elucidate the interaction characteristics of the $\text{O}_3\text{-H}_2\text{O}_2$ complexes. Two different intermolecular interactions were predicted that aid in the formation of complexes, namely: conventional $\text{O}\cdots\text{H}$ hydrogen bond and $\text{O}\cdots\text{O}$ contact. The hope of synthesizing a powerful, heretofore unknown oxidizer by reaction of H_2O_2 and O_3 is fading.

4.4.2.1 Reaction Mechanisms of H_2O_2 Reactions with Halogens

The reaction of H_2O_2 with chlorine and alkali and subsequent reactions with iodine are key steps in the operation of chemical oxygen iodine lasers (COIL). The laser is fed with gaseous chlorine, molecular iodine, and an aqueous mixture of hydrogen peroxide and potassium hydroxide (or $\text{KOH}/\text{NaOH}/\text{LiOH}$). The COIL output wavelength is $1.315\mu\text{m}$, the wavelength of transition of atomic iodine.

Because the oxygen thus formed is released in an excited state as singlet Δ oxygen (as indicated by the asterisk) and because spontaneous transition of excited oxygen to the triplet Σ ground state is forbidden by quantum mechanics, the excited atomic oxygen has a spontaneous lifetime of about 45 min. This allows the singlet Δ oxygen to transfer its energy to the iodine molecules injected to the gas stream which are nearly resonant with the singlet oxygen, so the energy transfer during the collision of the particles is rapid. The excited iodine then undergoes stimulated emission and lases at $1.315\mu\text{m}$ in the optical resonator region of the laser. The COIL has four primary parts: oxygen generator, gain generator (or resonator), pressure recovery system, and storage tanks that hold all the chemicals needed to operate the laser. Directed energy from the laser weapon would heat the incoming threat missile body, causing overpressure and/or stress fracture, which would destroy the hostile missile. The COIL was planned to be mounted on an aircraft and flown at high altitudes to detect, track, and destroy threat missiles in the boost phase, but the Airborne Laser program was eventually canceled in 2008; see also [389].

4.4.2.2 Reactions of H₂O₂ with Nitrogen Oxides

Reaction of H₂O₂ with NO

The reaction of H₂O₂ with NO in alkaline solutions will form peroxonitrites

This reaction may occur *in vivo*, since both H₂O₂ and NO are formed in various metabolic and nerve conduction processes. The anion is stable, but the free acid will decompose to nitrate with a rate of 1.3 s⁻¹ at 298 K.

The addition of fresh or decomposing H₂O₂ (a source of hydroxyl-free radicals) to stack gases from fossil fuel burning power plants is one of the methods suggested to clean up the stack gases by quickly oxidizing NO to NO₂, which is then removed by conventional DeNO_x processes [390].

Reaction of H₂O₂ with NO₂ or N₂O₄

The reaction of H₂O₂ with NO₂ is one of the key reactions in atmospheric smog formation under the influence of ultraviolet light from the sun. The reaction in the presence of water may lead to pernitric acid. Subsequent reactions with organics lead to peracetic acid, a nasty irritant.

4.4.3 Reactions of H₂O₂ with Organic Compounds

4.4.3.1 Reactions of H₂O₂ with Organic Amines

Mixtures of H₂O₂ with organic amines could potentially be used as monopropellants that are more energetic than H₂O₂ by itself (if they do not autoignite or explode during mixing). The freezing points of mixtures of 98% H₂O₂ with a selection of organic aliphatic, aromatic, and heterocyclic amines were determined [210]. The H₂O₂ and the amines formed adducts with peritectics and showed one or two eutectics. In several cases, the adducts could be isolated and showed stoichiometric composition of 2:1, 3:1 or 4:1 adducts. It was found that the peroxide remained stable and the amine unoxidized, as long as they were kept at low temperatures, that is, below 273 K (0 °C). If the solutions were allowed to warm up to room temperature, some of the amines caused decomposition of the peroxide, with oxidation of the amine to the nitro compound. Piperidine was the most active in producing decomposition and when warmed to room temperature, the heat of the reaction was enough to accelerate it progressively until the peroxide decomposed with **explosive** violence. The monobutylamine with the tertiary carbon atom attached to the nitrogen was the most stable of the amines tried, no decomposition took place. No crystals could be formed at the higher concentrations of the organic base since the mixture froze to a glass once the first eutectic had been passed. Even if they do not autoignite, these mixtures are **detonable**.

4.4.3.2 Reactions of H_2O_2 with Organic Amides

The reaction of H_2O_2 with urea produces urea peroxohydrate, CAS RN [124-43-6], which is industrially important as a solid form of hydrogen peroxide and can be used as topical disinfectant, mouthwash, and chemical oxidant. The optimum conditions for preparing urea peroxide were obtained as follows: molar ratio of hydrogen peroxide to urea 1.2; reaction temperature 298 K (25 °C); reaction time 30 min; mass ratio of stabilizer to urea 0.2%. Salicylic acid is suitable as a stabilizer [391].

4.4.3.3 Reactions of H_2O_2 with Ketones

The use of dilute H_2O_2 and/or acetone to clean laboratory equipment is common, but it has been shown to be potentially hazardous due to reactions of H_2O_2 with organic solvents that can form explosive peroxides. Mixing concentrated H_2O_2 and acetone with an acid catalyst is known to form the shock and friction sensitive explosives triacetone triperoxide (TATP) and diacetone diperoxide (DADP). When studying the potential formation of explosive peroxides when mixing dilute H_2O_2 and acetone solutions, the conclusion of these experiments was that when mixing dilute solutions, such as less than 3% H_2O_2 and 7% acetone, the solutions are unlikely to form significant amounts of TATP or DADP [392]. In the presence of an acid catalyst, hundreds of parts per million of organic peroxides can be formed. Although TATP is relatively insoluble in water, it is soluble at roughly the 15 ppm level and higher for acetone and H_2O_2 solutions, thus any acetone peroxides that are formed without an acid catalyst should remain soluble in the aqueous cleaning solution. If they were to precipitate, that would be a hazard.

4.5 Slow Homogenous Decomposition in the Liquid Phase

The following discussion of the decomposition of hydrogen peroxide in the liquid phase and in the vapor phase is restricted to decomposition as it relates to storage and handling. The controlled and deliberate decomposition of hydrogen peroxide such as in monopropellant rocket engines and gas generators will be discussed in *Encyclopedia of Monopropellants*. Many decomposition mechanisms (predominantly those based on homogeneous or heterogeneous catalysts) are suitable for the design of igniters for H_2O_2 rocket engines.

Unless a droplet of hydrogen peroxide is suspended in a weightless condition in outer space, where it will not be in contact with a container wall, it is very difficult to study the stability of H_2O_2 under terrestrial conditions in a gravity field without interfering effects from contact with the wall. Any contact with a wall is likely to alter the results of homogeneous liquid decomposition measurements. Flasks and tanks used for storage stability experiments have always been meticulously cleaned and passivated to minimize wall effects.

Methods for measuring the rate of decomposition of HTP are described in Section 4.7. Homogeneous decomposition rates for pure HTP in the absence of contaminants or stabilizers reported in the literature vary widely, depending on the source of the pure or ultrapure H_2O_2 and on the experimental conditions, such as the container material and exclusion of light and other stimuli.

4.5.1 Effect of Water Content on Slow H_2O_2 Decomposition in the Liquid Phase

Most other unstable compounds (e.g., hydroxylamine free base) may be relatively stable in aqueous solution and become increasingly unstable when the solution is more concentrated or when all water is removed to obtain the compound in the anhydrous state. In the case of hydrogen peroxide, the opposite may be the case, and a contradictory observation has been made repeatedly that the highly purified H_2O_2 is more stable than 70–90% aqueous solutions.

This unusual phenomenon has sometimes been used to test the compatibility of large hydrogen peroxide containers by exposing them not to high concentration hydrogen peroxide (for which they were intended) but to lower concentration hydrogen peroxide, as this would be a more stressing test of the compatibility and cleanliness of the tank. If the tank does not show excessive reactivity with low concentration hydrogen peroxide solutions, the compatibility should improve as the concentration increases. This is somewhat counterintuitive in that it suggests that very high concentrations of hydrogen peroxide, such as 98% or anhydrous hydrogen peroxide, are more stable than 90 or 70% and, therefore, potentially safer to store. Different explanations have been offered for this dependency, such as hydrogen peroxide and water forming clusters in which the H_2O_2 molecule is more stressed. It is unlikely that changes in surface tension can have any effect on H_2O_2 stability in solutions.

One must differentiate if one compares stability of solutions from which water has been removed, allowing accumulation of stabilizer in the less volatile residue or solutions (dilutions) made by adding ultrapure water to ultrapure, near 100% H_2O_2 . In the latter case, not only the H_2O_2 is diluted, but also the stabilizer concentrations decreased proportionally. In some cases, 98% H_2O_2 may be more stable than 90% H_2O_2 because, depending on the concentrating process used, the contaminants may be removed during the last concentration step, or the stabilizer may accumulate in the residue.

On the other hand, it is surprising to learn that when 90% unstabilized H_2O_2 was diluted with doubly distilled, very pure water under extremely clean conditions, the dilute solutions decomposed at a faster rate than the concentrated stock solution. This observation seems to counter what one intuitively would expect from concentrated energetic materials and their solutions.

4.5.2 Effect of Temperature on Slow Decomposition in the Liquid Phase

Data for the rate of decomposition of HTP as a function of temperature are listed in Table 41.

Table 41: Effect of temperature on decomposition of 90% hydrogen peroxide.

Temperature			Approximate rate of decomposition
K	°C	°F	
	30	86	1% per year
	66	151	1% per week
	100	212	2% in 24 h
	140	284	Decomposes rapidly with boiling

Data source: [367]

Commercial 90 and 98% hydrogen peroxide, maintained at 213 K (−60 °C) in the solid state, decomposed at a rate of less than 1 ppm per day [393]. As this was the order of magnitude of detection of decomposition in the equipment used at that time, it was believed that under these conditions high strength hydrogen peroxide can be considered stable and storable (less than 0.1% decomposition in 3 years).

Stability characteristics of concentrated hydrogen peroxide solutions have been studied at 323 to 373 K (50 to 100 °C) over the range 70 to 90 weight-% hydrogen peroxide in both the absence and the presence of stabilizers [308]. A temperature of 323 K (50 °C) proved satisfactory for the accuracy of the gas evolution method used to determine the rate of decomposition of peroxide samples. Previous reports [367] of high stability for very pure hydrogen peroxide at concentrations of 85 to 90% were confirmed. The temperature coefficient of the rate of decomposition of unstabilized H_2O_2 solutions was determined for the intervals 323 to 333 K (50 to 60 °C) and 333 to 343 K (60 to 70 °C) as 2.2 ± 0.1 , which is believed to be approximately applicable over any 10 °C range between 323 and 373 K (50 and 100 °C). Methods of preparing the surface of Pyrex[®] containers for use with concentrated hydrogen peroxide were developed, which make it possible to obtain reproducible measurements of the uncatalyzed decomposition rate. Pure aluminum and pure cast tin were found to be suitable materials of construction. Vigorous agitation was without appreciable effect on the measured rate of decomposition of 85% unstabilized hydrogen peroxide. The importance of pH on rate of decomposition was emphasized by measurements with and without added catalytic ions of known concentrations of ferric or cupric ion in 85 to 90% hydrogen peroxide at 323 K (50 °C) and on the required concentrations of stabilizers to counteract such catalytic action; see also [394, 395].

In the range between 343 and 363 K (70 and 90 °C), the rate of decomposition of highly pure, unstabilized H_2O_2 increases by a factor of 2.2 for every 10 °C increase in temperature. This temperature dependence agrees quite well with the rule-of-thumb

for many chemical reactions that the rate doubles for each 10° increment of temperature increase.

In some cases, 98% H_2O_2 may be more stable than 90% H_2O_2 because, depending on the concentrating process used, the contaminants may have been removed along with water during the last concentration step, or the non-volatile stabilizer may have accumulated in the residue. Depending on the storage conditions, decomposition rates of 1%/year must be assumed as acceptable for 98% H_2O_2 . The same material may lose 2%/day if it is stored at 373 K (100°C).

The measured decomposition rate of 0.014%/day at 323 K (50°C) for commercial 70% H_2O_2 [396] agreed well with previously published data since it lies between minimum reported values for stabilized and unstabilized hydrogen peroxide [308]. It was concluded that the peroxide used in these tests must have been a stabilized commercial grade. However, no chemical tests for the presence of stabilizers were made. Figure 43 is a plot of the decomposition rates calculated from oxygen evolution volumes versus temperature, derived from measurements at up to 408 K (135°C). The slope of the graph equals the log of the temperature coefficient a . A value of 2.08 was measured for a in this work illustrated in Figure 43.

Figure 43: Decomposition rate of 70% commercial grade hydrogen peroxide. (Reproduced and modified from [396].)

The exothermic decomposition process of H_2O_2 was examined by an adiabatic calorimetric method in order to better understand explosion accidents caused by H_2O_2 [397]. It was shown that the initial exothermic temperature for 30 mass-% H_2O_2 was 307.65 K (34.5°C), with the reaction heat being 301 J/g, the maximum self-heating

rate 35 °C/min, and the maximum explosion pressure per unit mass 1.7 MPa/g. It was also contemplated that timely cooling of a tank of decomposing H₂O₂ can prevent an explosion.

Thermal stability of 10, 20, 31, and 45 mass-% H₂O₂ (obtained from MGC Pure Chemical Taiwan, containing not specified stabilizers) was tested by differential scanning calorimetry (DSC) [398]. To build up a comprehensive kinetic model, various tests were conducted with heating rates of 1, 2, 4, and 10 °C/min, respectively. The experimental curves showed that H₂O₂ decomposition has one exothermic peak, and it may start to decompose below 320–354 K (47–81 °C). The activation energy and total heat of decomposition for three heating rates are summarized in Table 42.

Table 42: The thermokinetic parameters of 10, 20, and 31 mass-% H₂O₂ decomposition, as determined by DSC.

H ₂ O ₂ , mass-%	Heating rate, °C/min	<i>E_a</i> , kJ/ mol	<i>ΔH</i> , J/g
10	2	102.3	192.4
20	2	337.0	421.0
31	2	256.3	703.5
10	4	306.2	269.1
20	4	94.7	409.8
45	4	98.4	887.3
10	10	232.2	470.6
31	10	166.0	838.8
45	10	156.5	1078.5

Data source: [398]

There are plenty of data for activation energy of H₂O₂ decomposition at low to moderate concentrations (20–40% H₂O₂), but data are lacking for 70% and higher H₂O₂ concentrations (because they are more difficult to determine).

In a DSC with stainless steel sealed crucibles, the onset of decomposition of a commercial 50% H₂O₂ solution was at 340.5, 358.9, and 359.4 K (67.4, 85.8 and 86.3 °C) with heating rates of 3, 5, and 7 °C/min. [399]. The activation energy was 77.1 kJ/mol.

4.5.3 Effect of pH on Slow Decomposition in the Liquid Phase

The rate of decomposition of H₂O₂ is pH dependent. In alkaline solutions, the decomposition proceeds faster by several orders of magnitude than in acidic solutions. One industrial accident was caused by sudden decomposition of hydrogen peroxide in a caustic solution used in a chemical oxygen-iodine laser (COIL) test facility [400, 401].

A study of the role of pH on stability showed that a broad maximum in stability existed over a pH range of 0 to –2.5 (Figure 44).

Figure 44: Stability of 98% H_2O_2 as a function of pH. (Reproduced and modified from [402].)

The homogeneous decomposition of H_2O_2 in the absence of catalysts is dependent on the pH. H_2O_2 solutions are generally more stable in acidic solutions and less stable in alkaline solutions. In alkaline solutions, the autodissociation equilibrium

is shifted toward the right with the formation of HOO^- ions, which are unstable and accelerate the decomposition. Aqueous solutions of sodium peroxide are short-lived and decompose as soon as the sodium peroxide has dissolved. Strongly acidic additives (with the exception of phosphoric acid) accelerate the decomposition of HTP.

Exothermic decomposition of hydrogen peroxide due to contaminants has caused many industrial explosions. In one accident, H_2O_2 was mixed with H_2SO_4 in a vacuum tank truck, and an explosion occurred at that moment. The cause of the accident was that H_2SO_4 accelerated the decomposition of H_2O_2 and led to a runaway reaction. Runaway temperature explosion often occurs after an induction period. The thermal decomposition reaction of 20 mass-% H_2O_2 mixed with low (0.1, 0.5 or 1.0 N) or high concentrations of 96 mass-% H_2SO_4 was measured using DSC and a commercial instrument called Vent Sizing Package 2 (VSP2) [403]. Thermokinetic data, such as exothermic onset temperature (T_0), heat of decomposition (ΔH_d), pressure rise rate (dP/dt), and self-heating rate (dT/dt) were measured. The “piranha” solution (Caro’s acid solution), which is used to remove organic residues from semiconductor wafer substrates, has caused many accidents. In a printed circuit board manufacturing process, hydrogen peroxide mixed with sulfuric acid was used as the microetch chemical for copper surface roughening. The typical recipe is a 3:1 mixture of H_2SO_4 (96 mass-%) with H_2O_2 (20 mass-%). In this series of experiments, 30 mL of 20 mass-% H_2O_2 were mixed 10 mL of 0.1, 0.5, and 1.0 N H_2SO_4 . In another set of experiments, 2, 4, and 6 mL of 20 mass-% H_2O_2 were mixed with small amounts of 96 mass-% H_2SO_4 . When H_2O_2

solutions were acidified with small concentrations of H_2SO_4 , the reaction rate was observed to decrease to slower than that of pure, unadulterated 20 mass-% H_2O_2 . With gradually increasing concentration of acid, the rate increased to a reaction rate that was still slower than that of pure H_2O_2 , depending on the concentration of H_2SO_4 . When the H_2O_2 was mixed with concentrated H_2SO_4 , a violent reaction occurred immediately.

Hydrogen peroxide and hydrochloric acid are used in the semiconductor chip manufacture to clean silicon wafers. Inadvertent mixing has caused several accidents. Like the action of sulfuric acid, hydrochloric acid catalyzes the exothermic decomposition of H_2O_2 into oxygen and water.

Two-phase behavior in vessels, pressure relief valves, and vent piping is an important consideration in the design of chemical process equipment and associated safety relief systems. In order to investigate vapor-liquid two-phase flow behavior and proper size of venting systems, 12-N HCl was mixed with 30 mass-% H_2O_2 in different volume ratios from 1:15 to 1:2 [404].

In the 1980s, the accelerating rate calorimeter (ARC) allowed new advances in thermal hazard analysis, because it could record temperature and pressure data more accurately within the region of a self-decomposition reaction under approximately adiabatic conditions. Although ways to keep adiabatic conditions may be similar, test cell (bomb) and sensitivity are not the same in ARC as in other adiabatic calorimeters, such as Vent Sizing Package 2 (VSP2). Still, the operating procedures (heat-wait-search = H-W-S) are all the same. Vent Sizing Package 2 was used to separate catalytic and self-decomposition reactions for hydrogen peroxide in the presence of hydrochloric acid [405]. The standard operating procedure is a H-W-S cycle to find the onset temperature of a specific runaway reaction whose heat rate is equal to or greater than $0.05^\circ\text{C}/\text{min}$. The H-W-S operating method can only show the self-decomposition reaction. When HCl concentration decreases, the first catalytic reaction can be readily differentiated from the following second self-decomposition reaction. An improved operating procedure was used to find the slow first step catalytic reaction of hydrogen peroxide in the presence of hydrochloric acid. In these two reactions, the HCl concentration decreased with the activation energy of the first catalytic reaction and then increased with the activation energy of the second self-decomposition reaction. The temperature at which the catalytic and self-decomposition reactions intersect in the experiment operated by the improved method is the onset temperature of the experiment operated by the standard operating procedure. By the improved operating procedure, the duration of the first catalytic reaction increased while HCl concentration decreased.

The reactions of hydrogen peroxide in the presence of hydrochloric acid were studied by using an RSST adiabatic calorimeter [406]. The experimental data obtained from the RSST included the transient temperature profile, the transient pressure profile, the transient temperature variation profile, the transient pressure variation profile, and the heat of reaction. This violent reaction and the accumulation of heat and

non-condensable gas increase temperature and pressure in this reaction and lead to runaway reaction and overpressurization in a closed vessel. It was necessary to estimate kinetic parameters at various volumetric ratios of H_2O_2 to hydrochloric acid. Hydrogen peroxide with 30 mass-% H_2O_2 and hydrochloric acid with 37 mass-% HCl from Merck Co. were used without further purification and mixed in volumetric ratios of hydrogen peroxide to hydrochloric acid of 15:1, 7:1 or 4.33:1 for a total sample volume of 8 mL. It was concluded that the catalytic decomposition reaction of high concentration H_2O_2 by hydrochloric acid is a “non-tempered hybrid system”. The criteria of stability and runaway temperature with varying volumetric ratios of H_2O_2 to hydrochloric acid can be evaluated from their kinetic parameters and ambient temperatures. The critical ignition and quenching temperatures can be predicted based on geometric factors of the reacting vessel and heat loss to the environment.

At a pH value equal to 9, the decomposition rate of 30 mass-% H_2O_2 is highest, and this condition can lead to accidents [407].

In order to study the influence of pH on the thermal runaway reaction hazard of H_2O_2 , Vent Sizing Package 2 (VSP2) was used to analyze the thermal behavior of 27.5 mass-% H_2O_2 with different pH values of 1.8, 4, 5, 6, 7, or 8 under adiabatic conditions [408]. The time to the maximum reaction rate at 303 K (30 °C) under adiabatic conditions was obtained from the kinetics data. The results showed that as the pH value of H_2O_2 increased, the onset exothermic temperature decreased, and the time to the maximum reaction rate under adiabatic conditions got shorter and shorter, so the risk probability of thermal runaway increased significantly. When H_2O_2 is stored in the industrial conditions, there is a certain risk when the pH value is 6, and thermal runaway is almost inevitable when the pH value is more than 7.

Most of the bleaching of cellulose fibers and fiber products is done at high, alkaline pH, and the strength of hydrogen peroxide is quickly lost in the presence of metal ions. It was examined which metal ions are the most adverse and must be avoided to extend the life of the bleaching agent [409].

4.5.4 Wall Effects on Slow Decomposition in the Liquid Phase

There is a wide array of publications on the storage stability of hydrogen peroxide. It was extremely difficult to eliminate surface (wall) effects and measure the true homogeneous rate of decomposition of H_2O_2 .

Experiments at the Laporte laboratories in England, in which ground glass particles were mixed with H_2O_2 in small glass vessels in order to offer a large area of glass in contact with the H_2O_2 solution under test, indicated that the surface-to-volume ratio was without significant effect upon the observed decomposition rate. In an attempt to explore this process more completely, two sets of experiments were carried out at MIT [309]. In one, the rate of decomposition of 90% H_2O_2 was measured in the usual way with a Pyrex[®] gas evolution flask filled with different volumes of the solution. The flasks used for this purpose were round 250 mL flasks with flattened bottoms but an essentially round end with a radius near 4 cm. The surface area exposed was calcu-

lated from measurements of the height of the liquid in the flask. The volume of liquid was determined by weighing the amount of H_2O_2 of known concentration and density added to the flask. The variation of S/V ratio possible under these conditions was 0.8 to 1.5 cm^{-1} . It was found that the rate was the same when the flasks were half or totally full. Experiments with 40, 100, or 200 glass rods added to the flask and S/V ratios of 0.8 to 7 cm^{-1} at 323 K (50°C) led to the conclusion that the rate of decomposition is independent of the surface-to-volume ratio. If the procedure of adding more and more surface were carried far enough, the slope of the decomposition rate curve would decline to the horizontal, meaning that the rate of decomposition would be independent of the surface-to-volume ratio.

In another experiment, the primary objective was to study the homogeneous thermal decomposition in 100% H_2O_2 and arrive at a reasonable mechanism for the decomposition [410]. After spending a considerable effort to keep the experiments dust-free and make the quartz surfaces catalytically inactive, it was found that a homogeneous decomposition was still not achieved. Because of this result the work was not continued beyond the first stages of a kinetic study. In this study, spherical bulbs of fused quartz with a capacity of about 1 mL and weighing about 0.4 g were constructed from selected quartz tubing. The quartz vessels were cleaned and conditioned before use by the procedure recommended by Schumb. Hydrogen peroxide used in this work was purified by repeated recrystallization of concentrated 97.85% stabilizer-free material obtained from Buffalo Electric Co. The material was handled in quartz glassware under dust-free conditions. The hydrogen peroxide was purified by six crystallizations carried out in a closed system constructed in such a way that the H_2O_2 -enriched crystals always remained in the same flask. After crystallization, the material gave an analysis of 99.8% hydrogen peroxide by weight using a method of direct titration against potassium permanganate in dilute sulfuric acid solution.

A series of progress reports on early H_2O_2 characterization and the mechanism of autodecomposition work at MIT contains some of the information that was later included in a book by Schumb, Satterfield, and Wentworth [309, 376, 411–413]; see also [414].

There are some contradictions in these publications, but we have not attempted to referee the dispute. It is obvious that the rate of autodecomposition during storage of HTP is dependent on so many variables that it is difficult to make a comparison. Many early investigators failed to specify whether the HTP they tested contained a stabilizer, how much stabilizer, and which type(s) of stabilizer(s). One investigator [415] of early samples of HTP tested for storage stability reported that:

Commercial 90 and 98% hydrogen peroxide, maintained at -60°C in the solid state, decomposed at a rate of less than 1 ppm per day. As this was the order of magnitude of detection of decomposition in the equipment used it is believed that under these conditions high strength hydrogen peroxide can be considered stable and storable (less than 0.1% decomposition in 3 years).

Another series of stability tests on samples of commercial (stabilized) 90 and 98% hydrogen peroxide at 213, 243, and 273 K (−60, −30, and 0 °C) in Pyrex[®] glass showed that commercial grades of 98% and some commercial grades of 90% hydrogen peroxide available in the 1960s, maintained at 0 °C or below, can be considered stable and storable (decomposition rates below 1–0.5 ppm/d) [416]. These two quarterly reports were superseded by a more comprehensive final report [417]. That final report contains data on the low temperature 213, 243, and 273 K (−60, −30, and 0 °C) stability in Pyrex[®] glass of 90–100% hydrogen peroxide, on the effect of container surfaces on the stability of such peroxide in the 323–343 K (50–70 °C) temperature range, and on the mechanism of hydrogen peroxide decomposition. It was shown that carefully purified, or commercially stabilized, 90–100% hydrogen peroxide in Pyrex[®] glass at 213 to 273 K (−60 to 0 °C) was stable and storable, with less than 1 ppm per day (0.04% per year) decomposition. At higher temperatures, 323–343 K (50–70 °C), mildly irradiated Teflon fluorinated ethylene propylene (FEP) fluorocarbon as a container surface is exceedingly inert to high strength hydrogen peroxide, causing less than one-third of the peroxide decomposition of a passivated aluminum surface, and less than one-half of that of passivated Pyrex[®] glass. Using high purity (99.999% Al) aluminum instead of pure (99.95% Al) aluminum did not improve the quality of the passivating film of oxide formed on the surface. Studies of the sites of attack of hydrogen peroxide on aluminum surface, together with methods of following the mechanism of decomposition of hydrogen peroxide catalyzed by metal ions (both oxidizing and reducing) and radiation helped in the development of superior stabilization systems for hydrogen peroxide.

The rate of decomposition of 90 to 99% H₂O₂ at 323 K (50 °C) is proportional to the surface : volume ratio, based on experiments with Pyrex[®] vessels. The wall-catalyzed surface heterogeneous reactions are much faster than the homogeneous decomposition. Thus, the rate of decomposition in very large storage vessels is lower than in 55-gallon drums or smaller containers.

The container walls in the vapor phase that are not wetted by the liquid also contribute to the overall decomposition. The alkaline surface of common soda glass containers will catalyze the decomposition of H₂O₂. Coating the inside of a soft glass bottle with paraffin has greatly reduced the rate of decomposition of H₂O₂ solutions. Borosilicate glass like Pyrex[®] is less active than soda glass (“soft glass”) in this regard.

The question that is often raised is whether the storage stability of highly concentrated H₂O₂ is limited by dissolved contaminants or by contact with the walls of the tank material. Thus, in outer space in a zero-g state where in the absence of surface tension effects the hydrogen peroxide could float without being in contact with a wall, the storage stability might feasibly be improved. However, hydrogen peroxide has been used only in very few satellites, and no such space storage data are available. One genuine handicap in the space application of hydrogen peroxide is the need to vent the tank periodically to relieve the pressure caused by oxygen formation. It is

difficult to vent a tank in zero-g since some of the liquid may also inadvertently escape along with the gas/vapor phase.

4.5.5 Effect of Contaminants on Slow Decomposition in the Liquid Phase

The slow decomposition of H_2O_2 during storage of highly concentrated hydrogen peroxide is highly undesirable and has been investigated for many decades. It takes place even in high purity H_2O_2 and is catalyzed by traces of contaminants, suspended or dissolved, including ions of many transition metals such as Fe^{3+} , Cu^{2+} , Co^{2+} , Ni^{2+} , and metallic silver or platinum-group metals and their alloys (Section 4.10.2.1).

Table 43 gives a comparison of the effects of various metal salts dissolved in 90% H_2O_2 and heated to 373 K (100 °C). At a concentration of 0.1 mg/L, copper and chromium ion were the worst offenders.

Table 43: Effect of metal salt contaminants in 90% H_2O_2 .

Additive	Concentration, mg/L	% of original active oxygen lost during 24 h at 373 K (100 °C)
None		2
Copper	0.1	85
Copper	0.01	24
Aluminum	10	1
Iron	1.0	15
Chromium	0.1	96
Tin	10	2
Zinc	10	10

Data source: [367]

A wide range of contaminants, including 2-propanone, Fe_2O_3 , FeSO_4 , H_2SO_4 , HCl , HNO_3 , H_3PO_4 , NaOH , KOH , and LiOH was tested in a DSC for the decomposition of 10, 20, 31, and 45 mass-% H_2O_2 between 303 and 573 K (30 and 300 °C) in contact with a series of incompatible materials [418]. Most of the tests were performed with 31% H_2O_2 . The activation energy of the decomposition of unadulterated 31% H_2O_2 was $E_a = 336 \text{ kJ/mol}$.

A study of the effects of Fe^{3+} , Cr^{3+} , Ni^{2+} , and Mn^{2+} ions on the decomposition of 15% solutions of hydrogen peroxide in water showed that the ions Ni^{2+} and Mn^{2+} ions were ineffective in promoting decomposition, but Fe^{3+} and Cr^{3+} lead to significant decomposition at concentrations of 10 parts per million or greater [419].

The following tests were not really slow decomposition experiments because the 35% H_2O_2 solution was heated to 366–372 K (93–99 °C) to accelerate the process. The effect of nitric acid with and without additional iron or copper ions was determined by measuring the half-life time of 35% H_2O_2 under the test conditions [420]. The half-life time of H_2O_2 in 1.7-M HNO_3 at 366–372 K (93–99 °C) was 48000 s but decreased to 2800 s

in 4.1-M HNO_3 , 28 s in 8-M HNO_3 , and 0.3 s in 12-M HNO_3 . In the presence of 0.73 mg/L Fe^{3+} in 1.7-M HNO_3 , the half-life time of 3.4-M H_2O_2 was 36094 s but decreased steeply to 206 s at 95 mg/L and was down to 20 s at 1000 mg/L Fe^{3+} . Similarly, with Cu^{2+} ions, the half-life time of 3.4-M was 3208 s at 0.83 mg/L Cu^{2+} , 746 s at 108 mg/L, and 372 s at 1000 mg Cu^{2+} /L.

4.5.5.1 Effect of Iron Contaminants on Slow Decomposition in the Liquid Phase

The iron ion is the main contaminant that one would worry about when high purity H_2O_2 becomes inadvertently contaminated by contact with steel. In trying to improve storage stability of HTP, carefully controlled amounts of iron ion were added to HTP with and without the addition of stabilizers, and tests were performed to determine how much stabilizer is required to counteract (“neutralize”) the deleterious effect of iron ion contamination.

The catalytic decomposition of H_2O_2 by iron salts has been the subject of many investigations. The reaction has frequently been termed a ferric-ion catalyzed reaction in order to distinguish it from the reaction in which the ferrous ion is oxidized to a ferric ion by H_2O_2 without oxygen evolution; see also [421].

The catalytic effect of iron(III) perchlorate on the decomposition of H_2O_2 in aqueous solution has been studied at mol fractions of H_2O_2 up to 0.95 and at temperatures of 283, 298, and 313 K (10, 25, and 40 °C) [422]. The reaction is homogeneous, provided that the solution is kept sufficiently acidic, with a rate that was found to follow the expression

$$\frac{dX_p}{dt} = aX_p + bX_F^2$$

where X_F is the mol fraction of iron perchlorate, X_p is the mol fraction of hydrogen peroxide, and a and b are parameters dependent upon pH, temperature, and solvent composition. In concentrated solutions, both a and b are linear functions of $X_p/(1 - X_p)$. This was interpreted as arising from the replacement of molecules of water in the solvation shell of the ferric ion by molecules of peroxide to give ferric-peroxy complexes of the type $[\text{Fe}(\text{H}_2\text{O})_5(\text{H}_2\text{O}_2)]^{3+}$. The kinetics of the reaction most likely follow radical mechanisms.

The stabilizing effect of fluoride, sulfate, nitrate, phosphate, and pyrophosphate ions and sodium stannate was examined in $\text{H}_2\text{O}_2 + \text{H}_2\text{O}$ mixtures that were doped with iron(III) perchlorate as a catalyst [423]. Phosphate and pyrophosphate acted by precipitating inactive ferric salts from solution. No stabilizing effect was observed for nitrate ions. The other ions act in homogeneous solution by forming complexes with ferric ion. From the kinetic data the constants for complex formation were calculated, and it was shown that the presence of even one complex group in the coordination shell of the ferric ion was enough to make the ferric ion inactive. Sodium stannate yielded a colloidal solution, and its stabilizing effect is apparently the result of the adsorption of ferric ions on the colloidal particles. The stabilization showed a marked

time-dependence, and it seems probable that the catalytic ions become incorporated in the stannic-oxide lattice.

The fast thermal activity interpreter (FTAI) instrument was used to examine the chemical reactivity of commercially available 50% hydrogen peroxide at two different temperatures (303 and 313 K = 30 and 40 °C) both with and without contamination [424]. The results showed that at 303 K (30 °C) a small amount of rust (330 ppm) increased the reaction rate of 50% hydrogen peroxide already by a factor of 50. When the temperature was increased to 313 K (40 °C), the reaction rate was further increased by almost a factor of four. The implication for reactivity management is that at this contamination level most practical vessel sizes would require emergency venting capability. A safety evaluation was then performed to determine the emergency venting requirement for the safe transportation or storage of contaminated hydrogen peroxide. It was determined that for quantities of the material less than 33.4 L (5 gallons), conventional breather vents would be enough to accommodate the gas that evolved. However, for larger quantities, a safety relief device would be needed. For example, for a 1.5 m³ (400-gallon) tote bin at 313 K (40 °C) the required minimum vent area was estimated to be 27.7 cm² (4.3 in.²), corresponding to a minimum vent diameter of 5.8 cm (2.3 in.).

The adiabatic temperature increase of both closed and open systems and the pressure increase for closed systems were used as a measure of severity of the assessment criteria. The time to maximum rate (TMR_{ad}) may be an indicator for the probability of occurrence of a runaway reaction scenario. The results at 293 K (20 °C) showed that a small amount of Fe³⁺ (12.7 mg/L) reduced the TMR_{ad} of 30 mass-% H₂O₂ by almost a factor of 11 [425].

4.5.5.2 Effect of Non-ferrous Metal Contaminants on Slow Decomposition in the Liquid Phase

Many other metal ions other than ferrous and ferric ion are active catalysts in the decomposition of hydrogen peroxide and will accelerate the rate of gas and heat evolution and lower the temperature threshold beyond which the process becomes autocatalytic and results in a thermal runaway situation. One of the most active ions in this regard is copper. Although much of the work on the effect of contaminants on the stability of H₂O₂ reported in the literature has been carried out with intermediate concentrations (30–45% H₂O₂), the same contaminants would also wreak havoc in rocket-grade hydrogen peroxide (RGHP).

On the Metropolitan Expressway in Tokyo, a tank car exploded because it was carrying H₂O₂ in a compartment in which some copper(II) chloride (CuCl₂) accidentally remained. An experimental investigation in a reaction calorimeter of the catalytic activity of CuCl₂, in comparison to two other copper(II) compounds [nitrate: Cu(NO₃)₂ and copper sulfate: CuSO₄] and three iron(III) compounds [FeCl₃, Fe(NO₃)₃, Fe₂(SO₄)₃] revealed that during the experiments at 308 K (35 °C), 2 × 10⁻⁵ mol of copper compounds slowly reacted with H₂O₂ and generated a precipitate [426]. A 1 × 10⁻⁴ mol

solution of CuCl_2 produced a violent decomposition at 308 K (35°C). At 288 K (15°C), only a moderate heat release occurred. The iron compounds caused the H_2O_2 to decompose violently at all temperatures.

The effect of various concentrations of Cu^{2+} ion (added in the form of Cu(II)Cl_2 solutions) and initial temperature on the heating rate of 30% H_2O_2 was measured as part of an investigation into the explosion of a waste-liquid hauling truck in Japan [427]. The testing was done in a simple glass test tube with an immersed, Teflon-coated thermocouple. For Cu^{2+} concentrations at or below 0.02 mass-%, no cook-off occurred, and the heat was conducted away safely. For Cu^{2+} concentrations of 0.04, 0.05, 0.075, 0.115, 0.144, and 0.172 mass-%, a cook-off spike occurred within 100 to 5 min. When the Cu^{2+} concentration was over 0.25%, the mixture spattered immediately on adding the ion. For the intermediate concentration, 0.075 mass-% Cu^{2+} , the energy of activation in the range from 298 to 308 K (25 to 35°C) was 32.3 kJ/mol.

In continuation of these tests, other contaminants in addition to copper ion were tested [428]. In order to avoid any interfering catalytic effects, glass vessels were used, whereas VSP2, RSST, and ARC use metal vessels. Moreover, as the runaway reaction was confirmed visually, a considerable quantity of hydrogen peroxide was used, as opposed to <1 g sample sizes in DSC, VSP2, RSST, and some ARC tests. The concentration of slightly more than 30 mass-% H_2O_2 was adjusted by diluting 35 mass-% of hydrogen peroxide (Wako Chemicals Co. Ltd., stabilizer-free grade) with distilled water. Then, a calculated amount of aqueous solution containing a known contaminant was added to the H_2O_2 solution, so that the final concentration of H_2O_2 was exactly 30 mass-%, and a desired concentration of metal ion obtained. Iron, copper, or chlorine ions accelerated the runaway reaction, but nickel, potassium, sulfate, and nitrate ions had little effect. CuCl_2 accelerated the decomposition more slowly than the iron compounds. The color of the hydrogen peroxide solution changed to dark brown, and suspended particles were gradually produced when the CuCl_2 blue solution was added. After the runaway reaction ended, these particles disappeared, and the color of the solution returned to be blue. The same brown particles were also found in the case of $\text{Cu(NO}_3)_2$ and CuSO_4 .

4.5.5.3 Effect of Organic Contaminants on Slow Decomposition in the Liquid Phase

Incompatible organic contaminants can not only accelerate the decomposition of H_2O_2 in the liquid phase, but they can also result in the formation of detonable mixtures. The main concern is with organics that are introduced inadvertently from lubricants, sealants, or plasticizers in contact with HTP. On the other hand, some organic compounds, such as oxin or ethylene diamine tetraacetic acid (EDTA) are added to H_2O_2 deliberately as stabilizers.

The reaction of hydrogen peroxide with 2-propanone (acetone) leads to formation of triacetone triperoxide, a powerful explosive. Many accidents have occurred during the illicit preparation of this compound for clandestine (terrorist) purposes [418].

Differential scanning calorimetry (DSC) and Vent Sizing Package 2 (VSP2) were used to evaluate the thermal hazard of H_2O_2 mixed with 2-propanone (acetone) [429]. The results indicated that H_2O_2 is highly hazardous when mixed with 2-propanone as a potential contaminant. The time to maximum rate (TMR) was used as emergency response time in the chemical industries. Whereas TMR of H_2O_2 alone was calculated to be 70 min for runaway reaction (after T_0), the TMR of H_2O_2 /propanone mixtures was reported to be only 27 min. The critical temperature T_c of 20 mass% H_2O_2 was determined to be 389 K (116 °C).

The specific impulse of HTP as a monopropellant can be improved by dissolving alkanol fuels in the oxidizer. The storability of 90% HTP/alkanol mixtures with oxidizer: fuel ratios of 10, 30, and 50 was tested for 39 days at room temperature [430]. The active oxygen loss in methanol was much worse than that in ethanol. Some of these HTP/alcohol mixtures are detonable.

4.5.6 Effect of Container Materials on the Decomposition of Hydrogen Peroxide

The decomposition of H_2O_2 is catalyzed on the surface of many materials, including the surface of materials in which it is stored. Inevitably, this decomposition continues even in the absence of surface contact (assuming a drop of H_2O_2 is suspended in a zero-g lab in outer space), but at a slower rate.

The use of concentrated hydrogen peroxide as a rocket propellant requires a knowledge of its effect upon materials that are likely to be used as containers, gaskets, propellant lines, etc., and of its stability in the presence of such materials. The effects of such materials on the stability of concentrated hydrogen peroxide were summarized soon after concentrated hydrogen peroxide first became available [431].

In order to identify the effect of the reaction vessel material on the slow decomposition of liquid HTP, a series of experiments using several different materials at different surface: volume ratios were carried out [432, p. 179–184]. For vessels made of molybdenum glass, opaque quartz, and (to a lesser degree) Pyrex[®] glass, the surface: volume ratio was found to significantly affect the HTP decomposition rate. However, if the vessel was made from Teflon or optical grade quartz, the decomposition rate was very slow, the lowest ever observed, and it was no longer dependent on the S/V ratio. The rate of decomposition remained unchanged even if the S/V was increased by a factor of 3 to 4. It is assumed that under these conditions the decomposition of H_2O_2 is that taking place in the homogeneous liquid as opposed on the heterogeneous surface. For commercial grade HTP (94–97% H_2O_2), the thermal effect was 2.75 ± 0.13 kJ/g as determined by calorimetry. The liquid phase decomposition of H_2O_2 was found to be a first-order reaction as indicated by the straight line in Figure 11.6 on page 180 of [432]. If one plots the rate of heat evolution against the reciprocal temperature (with constant degrees of conversion), one can derive the activation energy and pre-exponential factor from the slope and intercept of the Arrhenius curve as shown in Figure 11.8 on page 181 of [432]. These data were obtained with 96% H_2O_2 in reaction

vessels made of Teflon or optical grade quartz. In this case, $E_{\text{act}} = 85.8 \text{ kJ/mol}$ and $k_0 = 4.5 \times 10^5 \text{ s}^{-1}$.

In Russia, where hydrogen peroxide continues to be used for a variety of rocket propulsion applications, it has become common practice to characterize different samples of HTP by a so-called *thermal stability index* (TSI). The TSI is defined as the amount of oxygen in cm^3 at standard temperature and pressure (STP) evolved from a sample of 50 mL HTP heated in a glass flask at 369 K (96°C) for 1 h. It was attempted to establish a correlation between the TSI and the kinetic constants of homogeneous HTP decomposition. The TSI did not influence the effective activation energy. In contrast, the pre-exponential factor in the expression for the rate constant increased linearly with the TSI. That indicates that the TSI is due to the homogeneous decomposition. Data obtained for various HTP samples with different initial TSI values can be plotted in Arrhenius coordinates as one straight line with a normalized TSI. Data obtained with two different methods, volumetric and calorimetric methods, fall on the same line as shown in Figure 11.11 on page 182 of [432]. The kinetic rate equation derived from these data is

$$k = 4.8 \times 10^5 \exp\left(-\frac{20800}{RT}\right)$$

where k is the rate constant in s^{-1} , and T is the temperature in kelvin. These experiments were then repeated for HTP in contact with various metals of construction. The highest rates of decomposition were observed for HTP in contact with niobium (=columbium) and nickel, and the lowest rates were observed on aluminum. The kinetic rates were then used to calculate the temperature at which the decomposition becomes self-accelerating under adiabatic conditions and results in a run-away reaction, which quickly leads to rupture of any container. The threshold temperature can be calculated using the Semenov theory equations.

4.6 Results of Long-Term Ground Storage Tests with HTP H_2O_2

There are numerous storage stability tests described in the literature, but it is difficult to bring them to a common denominator. The main reasons for differing results and results not reproducible at other organizations are the different passivation methods used for storage containers prior to filling them with HTP, and errors that may have slipped in during sampling and analysis. Alone the act of taking a grab sample from a storage test in progress is already apt to unwittingly introduce contaminants and alter the results. The volume:surface ratio and the climate of the environment where the hydrogen peroxide drums or spherical tanks are stored has a major effect on the rate of decomposition. For space applications, extrapolation from ground storage tests to in-space predicted useful life span has not been very accurate. In-orbit

reaction control systems using hydrogen peroxide have demonstrated space storability in excess of 2 years (with an estimated predicted storability of 5 years). Long-term in-space storability depends on a reliable method for venting excess gas pressure without spilling any liquid that would still be needed for the rest of the mission. Surface tension passive propellant management devices would allow liquid/gas phase separation in a zero-g environment, but they would add a lot of surface area and speed up decomposition of H_2O_2 . Spinning satellites or pre-venting propellant settling by use of a cold gas thruster system would be the only good phase separation method but takes a lot of extra weight.

Hydrogen peroxide ground storage tests were conducted during the 1950s and 1960s by most of the HTP manufacturers in the US to demonstrate the reliability and marketability of their product.

Four grades of Becco H_2O_2 were evaluated for storage in sealed storage containers: commercial 90% by weight H_2O_2 , propulsion-grade 90% by weight H_2O_2 , commercial 98% by weight H_2O_2 , and propulsion grade 98% by weight H_2O_2 , in 1-gallon capacity TFE Teflon bladders contained in mild steel test tanks at 293–294 K (70–72 °F) for 5 months, 322 K (120 °F) for 7 days, and 347 K (165 °F) for 72 h [433]. The bladders were not as compatible as desired due to the bleaching and crack development experienced with this dispersion-type Teflon. Tests showed that the oxygen loss from the H_2O_2 during storage can be decreased by improved passivation techniques, surface pretreatment techniques, and improved stabilizers. The most promising test results were obtained with the 98% propulsion-grade HTP containing phosphate stabilizer.

In parallel, storage tests were conducted by US Government agencies such as National Aeronautics and Space Administration (NASA), former National Advisory Committee for Aeronautics (NACA), Jet Propulsion Laboratory (JPL) and Air Force Research Laboratory (AFRL) to verify the storability claims advertised by the propellant suppliers. In between, propulsion system manufacturers ran their own storage and materials compatibility tests. It is impossible to summarize all that information and, in many cases, it is not worth being summarized and preserved for posterity.

The Shell Development Co., Emeryville, CA, a division of the HTP manufacturer Shell Chemical, conducted storage tests with HTP of different pedigree and attempted to purify HTP by passing it through an ion exchange resin. Samples of HTP that had been further purified by ion exchange, distillation, or recrystallization were placed in storage at 25 °C along with stabilized samples prepared under a previous contract [434–436]. Samples were stored in Aclar[®]-lined (a fluoropolymer film) vessels and tin-plated aluminum or steel vessels in addition to Pyrex[®] vessels for comparison of the relative activities of these surfaces toward decomposition of HTP. Two vessels of type 1260 aluminum previously in use with HP in storage were heat-treated with HTP in order to reduce their surface activity and were then refilled with HTP and returned to storage for several more years. Samples thus purified by ion exchange immediately prior to filling the 5-gallon storage containers were stored for over 1 year at 298 K and suffered active oxygen losses of less than 0.1%/year [166]. Pressure buildup during

extended storage of HTP in closed vessels (sealed storage with no pressure relief valve) is a major concern, and a hurdle that has not yet been mastered.

Outdoor covered storage of FMC propulsion grade 98 mass-% HTP at Aerojet Missile and Space Propulsion in 30-gallon as-received aluminum shipping containers (2.5 year storage time) resulted in an apparent decay of 1 to 1.5% concentration per year, measured by a comparison of three different assay methods, as shown in Figure 45. At the 2.5-year point, assay results ranged from 95.3 to 96.2 mass-%, down from the original as-received value of 98.9 mass-% HTP [437].

Figure 45: Decay of assay of 98 mass-% HTP as a function of storage time. (Reproduced and modified from [437].)

It has been reported [438] that in a single drum of 90% propellant-grade hydrogen peroxide which had been in storage at FMC for over 17 years, the concentration of this drum started at 90 to 91% and after 17 years was measured at approximately 84%, which is just less than 0.4% drop in concentration per year. This drum had been stored outdoors in the ambient conditions of Texas. In addition, a second set of drums containing 90% hydrogen peroxide had been in storage at 278 K (5 °C) for over 17 years and have been measured at 90.5%. This demonstrates that at 278 K (5 °C) essentially no measurable decomposition occurred over 17 years. Some of these tests may have to be repeated under carefully controlled conditions, also stating the amount of stabilizer used.

During the 1998–2001 time frame, NASA Stennis Space Center (NASA SSC) stored H₂O₂ in 55 and 30-gallon drums near the E-3 test facility. In April 2001, four drums of 98% concentration peroxide were discovered to be expelling their contents from vent holes and around the top clamping ring [439, 440]. Out of an abundance of caution, the contents of the drums were safely pumped into a disposal area and disposed of.

Seven additional drums were similarly disposed of when they were found to be suspiciously warm. The vendor-supplied drums were stainless steel with a polyethylene lining. These drums failed to meet long-term storage requirements. NASA Stennis Space Center discontinued use of polyethylene lined stainless steel drums for long-term storage. From then on, vendor container designs were reviewed, inspected, and approved by NASA SSC personnel prior to acceptance.

4.7 Experimental Methods to Determine H_2O_2 Decomposition Rates

The stability of hydrogen peroxide is normally defined by two parameters: AOL and a term called the *stability*. The AOL parameter is defined as a value based upon a test at a specific temperature and duration for a set of propellant properties (concentration, purity, and stabilizer content) and a specific material of construction with or without surface passivation. A common test is an elevated temperature test at 339 K (66 °C) for 1 week. This is a type of an accelerated exposure test.

The homogeneous decomposition rate of hydrogen peroxide can be measured in the temperature range 318–532 K using any of or a combination of the following techniques:

- gravimetry
- manometry ($T = 350\text{--}430\text{ K}$, $p = 0.1\text{--}5\text{ MPa}$)
- volumetry ($T = 318\text{--}350\text{ K}$, atmospheric pressure) using a *microdroplet device* (Method I) or an *automated volumetric device* (AVD) (Method II)
- microcalorimetry

As part of a program to determine the hazards of 4000-gallon tanks with 70% H_2O_2 in an external fire, three different methods for measuring short-term H_2O_2 decomposition rates were evaluated [396]: measurement of (1) the volume of oxygen evolved, (2) the weight loss, or (3) the change in peroxide concentration. The first proved to be the most satisfactory method. The very small weight changes observed made the second method marginal. The third method was unsatisfactory due in part to the small concentration changes experienced. Furthermore, an analytical precision of not less than 0.01% was required, and this was not obtainable. Both the second and third methods are more appropriate for long-term tests, or tests where large changes in concentration occur. The weight of the reaction tube was measured on an oversized analytical balance accurate to about 0.5 mg. Weight losses were usually under 100 mg, and rates calculated therefrom had an accuracy of only 5 to 10%. The peroxide concentration was determined by titration of a small sample or aliquot with standard 0.2N ceric ammonium sulfate. The precision of the analysis was 0.2% or better. However, this equated to a precision of only about $\pm 50\%$ in the calculated decomposition rate. Thus, the titration method is unsuitable with small changes in concentration of peroxide.

4.7.1 Gravimetric Methods

The simplest, but not the most accurate method for determining the storage stability of HTP in contact with candidate materials of construction is to weigh the flask, HTP, and sample coupon together before and after keeping it in a thermostatted bath for a known length of time and allowing the evolved oxygen to vent, causing a weight loss. Based on the results of such a test, the materials can then be classified as suitable for long-term exposure or suitable only for short-term exposure, such as in a transfer hose that gets rinsed out after each use.

A common AOL test method for testing for classification used a sample coupon 3 in. $\times$ 0.5 in. $\times$ 0.0625 in., which would be cleaned, treated, and processed as closely as possible to the actual material being used [438]. This coupon sample size has a surface to volume ratio of approximately 0.33 in.⁻¹ when tested in 75 mL of hydrogen peroxide, simulating the surface to volume ratio of a typical hydrogen peroxide drum. The sample is placed in a clean and passivated 100-mL glass flask and weighed to an accuracy of ± 0.01 g. Hydrogen peroxide of a known initial concentration C_1 is added to the flask, and the flask is weighed again to obtain M_1 . The flask neck is covered with a 10-mL beaker. The flask is placed in a constant temperature bath for specific test temperature and duration, such as 339 K (66 °C) for 1 week. At the end of the test, the flask is removed and cooled. The 10-mL beaker is removed, the flask and contents are weighed again, and the final concentration C_2 of the hydrogen peroxide is determined. The final hydrogen peroxide mass M_2 is obtained from the difference between the final mass of the flask, fluid, and sample from the initial dry mass of the flask and sample. The AOL is calculated as:

$$\text{AOL} = 100\% \times \frac{M_1 C_1 - M_2 C_2}{M_2 C_2}$$

After the AOL test, a sample of the final hydrogen peroxide is typically subjected to a stability test to see whether any leached contaminants have altered its stability in the absence of the coupon. A cleaned and passivated 50-mL volumetric flask is filled to 50 mL with hydrogen peroxide from the AOL test. The flask is weighed to ± 0.01 g, giving the initial mass M_1 . The flask is covered with a 10-mL beaker and immersed in a constant temperature bath at 373 K (100 °C) for 24 h. After 24 h, the flask is removed and allowed to cool. The 10-mL beaker is removed and the flask is reweighed to determine the final mass. The stability is defined as:

$$\text{Stability} = 100\% \times \frac{(50 \times \rho \times C \times 0.47) - (W_1 - W_2)}{50 \times \rho \times 0.47}$$

where ρ is the density of the hydrogen peroxide, and C is the concentration of the hydrogen peroxide at the beginning of the test. Both these methods are inaccurate because not only oxygen but also HTP vapor and water vapor will escape during the test and cause mass loss.

4.7.2 Manometric Methods

The pressure as a function of time can be measured by standard manometers installed on thermostatted closed containers containing hydrogen peroxide (Method III).

4.7.3 Volumetric Methods

If there is any doubt about the storage and thermal stability of HTP for a specific application, one can conduct an accelerated aging test at elevated temperature and measure the amount of oxygen formed. One method heats the sample to 373 K (100 °C) for 1 h and measures the amount of oxygen formed gasometrically.

This method can also be used to compare the efficiency of different stabilizers. Working with 90–99% H_2O_2 solutions, it was noticed that as one approaches 98% H_2O_2 , the effectiveness of stabilizers is diminished or even reversed [307]. It appears that above 98%, the heterogeneous reactions with walls and the autodecomposition of hydrogen peroxide prevail. A comparison of the accelerated manometric method with long-term standing tests in 20–50-L containers at 298 K and periodic H_2O_2 concentration analysis of grab samples showed that over a 150-fold range of decomposition rates, the correlation between the two methods was linear and was usually within a factor of 2. This was taken as a validation of the accelerated volumetric method.

An AVD consists of an automated gas burette with a compensation vessel that moves up and down via a reversible motor [432, there p. 175–176]. A U-tube gauge responding to the pressure change in the sealed system in which decomposition of the liquid takes place is used as a sensor. As gas collects in the system, the compensation vessel moves down and drags a recorder ink pen over a moving paper strip driven by a synchronous motor. When the burette is completely filled with gas (in the lowest position of the compensation vessel), an electric contact triggers the lifting of the compensation vessel by the reversible motor, while gas is released to ambient air through a check valve. At the uppermost position of the compensation vessel another electric contact stops the reversible motor. The curve registered on the paper is, thus, a series of zigzag lines from which the rate of gas evolution can be calculated.

Another device is the *microdroplet device*, which is based on displacement of an inert liquid from a small reservoir (sitting inside a large round-bottom flask) with an inserted capillary dip tube by gas evolved from a propellant sample in a closed 1-L flask kept at constant pressure and temperature. The small reservoir and the main flask share the vapor space. The change in the volume of the displaced liquid is identical to the volume of the evolved gas and is recorded as a function of time. The liquid displaced from the vessel connected to the reaction flask drops from a capillary into a collector dish sitting on a recording digital scale. The amount of gas evolved is determined by periodically weighing the collector dish (the density of the liquid is known, and it must be assumed that none of the evolved gas dissolves in the liquid and that the liquid density remains constant). In addition, one can count the number of droplets by placing the droplet path into the path of light from a light source to a photocell and

separately measure the mass of 10 or 100 droplets. High sensitivity was achieved by using perfluorinated liquids characterized by a low surface tension and forming very small droplets of a constant volume ($V = 10^{-3} \text{ cm}^3$) but ignoring evaporation losses from the perfluorinated liquid.

A method for volumetrically measuring oxygen evolution as a means to monitor peroxide stability in stationary storage tanks instead of immersing a thermocouple avoids any penetrations of the tank wall to insert temperature probes [441, 442]. Measuring liquid peroxide temperature to monitor peroxide stability has significant limitations. The bulk decomposition of 0.75%/week (dump limit) from 276 lb_m of 90% HTP in a large volume tank at 25 °C produces 30 mL of gas. This flow rate corresponds to an equivalent temperature rise of approximately 14 millidegrees C, which is difficult to measure reliably. Thus, if heat transfer were included, there would be no measurable temperature rise. Temperature changes from the surrounding environment and heat lost to the peroxide will also mask potential problems. The use of oxygen flow measurements provides a more sensitive technique for monitoring stationary tank contents and will provide an earlier indication of an abnormal decomposition when compared to relying on temperature rise measurements.

For measuring the rate of decomposition of commercial 70% H₂O₂ exposed to a bonfire, a Pyrex[®] reaction vessel supported in an insulated thermostatted water bath was connected through capillary tubing to a water-jacketed gas burette with a leveling bulb [396]. The reaction vessels were heavy wall Pyrex[®] tubes 9 in. long by 1 in. diameter. An integral upper tube 8 in. long by 0.4-in. outer diameter (OD) extending above the bath, permitted any escaping water vapor to condense and flow back. The volume of these tubes was 57 mL. The reaction tubes were cleaned by standing filled with concentrated nitric acid for 24 h or more, followed by thorough rinsing with distilled water. They were then preconditioned by standing with 70% hydrogen peroxide.

4.7.4 Calorimetric Methods

Calorimetric methods are suitable for the automatic measurement of the decomposition rates of hydrogen peroxide at ambient temperature [443], but it was not until the sensitivity of calorimeters was improved by several orders of magnitude that such methods actually found practical applications. An ultrasensitive heat measurement technique, isothermal microcalorimetry, was used at the NASA White Sands Test Facility to monitor the decomposition of hydrogen peroxide at near ambient temperatures [444, 445]. Isothermal microcalorimetry measures the heat flow from a reaction vessel into a surrounding heat sink. The microcalorimeter instrument was able to detect heat releases as small as 5 μW. Microcalorimetry is approximately 1000 times more sensitive than accelerating rate calorimetry or differential scanning calorimetry for measuring thermal events. The decomposition rates of hydrogen peroxide at the picomols⁻¹ g⁻¹ level have been measured showing the effects of stabilizers and peroxide concentration. Typical measurements were carried out in 12-mL samples with and without ma-

terial test coupons at 40 °C over a 24-h period. Three different hydrogen peroxide solutions were used in these studies: commercial samples of nominally 70 and 85% solutions provided by Solvay Interlox, Inc. or a 90% solution supplied by FMC Corp. Analysis by permanganate titration showed the solutions to contain 69.5, 82.6, or 89.5% H_2O_2 , respectively. Analysis by inductively coupled plasma-mass spectroscopy indicated a tin content of 1.9 mg/kg and 1.6 mg/kg, respectively for the Solvay materials. FMC 90% propellant-grade H_2O_2 contains 1 to 2.9 ppm tin. Phosphate and sulfate were present at less than 1 mg/kg in all samples as shown by ion chromatography. Portions of the Solvay samples were purified by vacuum distillation (<55 °C at approximately 1 mm Hg) in an all-glass/polytetrafluoroethylene (PTFE) rotary evaporator. The distillation raised the assays to 79.8 and 86.5% H_2O_2 . The distilled solutions showed less than 5 ppb tin (but tin is not volatile, how was it carried over?). The phosphate, sulfate, and nitrate concentrations, however, were only slightly lowered to less than 0.5 ppm. The purified materials were then stored in polyethylene containers. The bulk decomposition rate of 90% H_2O_2 at 298 K in the absence of incompatible storage tank materials was $21.8 \text{ picomols s}^{-1} \text{ g}^{-1}$. The bulk decomposition rate of 82.6% H_2O_2 at 298 K in the absence of incompatible storage tank materials was $5.9 \text{ picomols s}^{-1} \text{ g}^{-1}$. Materials tested in contact with various HTP concentrations were Haynes 214, Inco 600, Al-5254, Al-6061, CRES-304, tantalum, Tefzel, Kynar, FEP, and PTFE. PTFE was the most compatible material, and CRES 304 was the least compatible material. The decomposition rate data can be used to predict the pressure in a H_2O_2 -filled tank stored for a certain time at a constant temperature.

In continuation of these studies, Al-5254, a tank material, and CRES-316, a component (valve) material were tested in 90% HTP [446, 447]. The total volume of the samples in the microcalorimeter was approximately 20 mL. The background decomposition rate of HP in a passivated container was determined in triplicate at temperatures between 298 and 333 K (25 and 60 °C). These background heat rates were due to the decomposition of the HP on the surface of the glass container and bulk homogeneous decomposition. This background rate was normalized to the mass of peroxide. The average heat of decomposition rate per gram and the corresponding molar decomposition rate range from $21 \text{ picomols s}^{-1} \text{ g}^{-1}$ at 298 K (25 °C) to $300 \text{ picomols s}^{-1} \text{ g}^{-1}$ at 333 K (60 °C). Data for Al-5254, passivated CRES-316 and electropolished CRES-316 were measured at 298, 313, and 333 K (25, 40, and 60 °C) and the decomposition rates plotted versus $1/T$ on a semilogarithmic plot to obtain the activation energies from an Arrhenius plot. The results showed that Al-5254 was the best material, and passivated CRES-316 was the worst material, with electropolished CRES-316 being in between.

4.7.5 Optical Methods

An optical bubble detection technique was used to determine the stability margin of propellant-grade hydrogen peroxide (HTP) in run tanks by accelerating and visually

observing the decomposition of a small H_2O_2 sample in contact with a metal coupon, thus simulating the propellant/tank interface [448]. Small samples of 90% HTP were periodically withdrawn from a run tank over a 400-h period and introduced into a Petri dish containing a steel coupon similar to the tank material, but at elevated temperature. During the decomposition oxygen was given off, and bubbles were formed over the coupon surface. Measurements were then made with respect to bubble formation, size, and density over the metal coupon, and a suitable imaging technique was used to extract bubble density data from the video. The data were then compared to the observed stability in the run tank as measured by pressure rise. The data were used to derive a mass diffusion-controlled oxygen bubble growth model for hydrogen peroxide/metal interfaces.

4.7.6 Other Methods

A measurement of NMR transverse relaxation time T_2 and pH of aqueous H_2O_2 solutions allows a non-invasive *in-situ* quantitative determination of the H_2O_2 concentration [298, 449]. This method was applied to measure the time profile of the heterogeneously catalyzed H_2O_2 decomposition on catalyst pellets by monitoring the reactant concentration in the vicinity of the pellet or in a closed volume. This is a new method for contact-free and non-invasive on-line monitoring of H_2O_2 concentrations.

4.7.7 Kinetics of the Liquid-Phase Thermal Decomposition of Hydrogen Peroxide

The decomposition of hydrogen peroxide follows the overall global reaction

The theoretical adiabatic decomposition temperature for 100% H_2O_2 at 6.89 MPa (1000 psia) is 1275 K (1002°C).

4.7.7.1 Surface Effects on Liquid-Phase Thermal Decomposition of Hydrogen Peroxide

The surfaces of glass, quartz, and to a lesser degree, of Pyrex[®] glass, affect the rate of the thermal decomposition of liquid H_2O_2 [450]. The temperature dependence of the rate constant of the thermal decomposition of H_2O_2 is

$$k = 5 \times 10^5 \exp(-20800/RT) \text{ s}^{-1}$$

The rate of H_2O_2 decomposition increased with an increasing concentration of Fe^{3+} in the system, while the energy of activation of the decomposition was practically independent of the Fe^{3+} concentration. The H_2O_2 used in these studies was 96–97% obtained by vacuum distillation. It is assumed that it did not contain any stabilizers. The reaction vessel was optical quartz or Teflon. The temperature differential between the reaction vessel and a constant temperature bath was measured with thermocouples. The rising gas bubbles would stir the reacting mixture, there was no mechanical

stirrer. The kinetic constants were calculated from the differential thermograms. Initial experiments in molybdenum glass, opaque quartz, and Pyrex® showed a lot of scatter in the data. In optical quartz or Teflon, there was only a weak effect of the surface: volume ratio. Varying the surface: volume ratio by a factor of 3 to 4 did not affect the rate or activation energy data. Because iron ions are considered one of the main culprits in limiting the storage stability of HTP and iron can easily be leached from process equipment or storage tanks, the effect of iron ion addition on thermal stability of HTP was examined. The experimental conditions are summarized in Table 44.

Table 44: Effect of added iron³⁺ ion concentration in hydrogen peroxide decomposition experiments.

Sample No.	Fe ³⁺ concentration	Temperature range		Activation energy		Rate constant
	mass-%	K	°C	kJ/mol	kcal/mol	s ⁻¹
0	Original liquid	323–453	50–180	87.0	20.8	3.1×10^{-9}
1	10^{-5}	327–363	54–90	87.4	20.9	4.6×10^{-9}
2	5×10^{-5}	320–363	47–90	91.6	21.9	2.6×10^{-8}
3	1.3×10^{-4}	317–348	44–75	87.4	20.9	3.0×10^{-7}
4	5×10^{-4}	313.9–348.6	40.8–75.5	83.7	20.0	8.9×10^{-7}
5	1.5×10^{-3}	303–325.6	30–52.5	81.6	19.5	8.0×10^{-6}

Data source: [450]

The data from Table 44 are illustrated in Figure 46 and 47. The numbers on the lines in Figure 46 refer to the sample numbers in Table 44. As one can see, the slope of the Arrhenius curves remains pretty well the same. In a double-log plot in Figure 47, the log of the kinetic rate at 323 K increased linearly with the log of the iron ion concentration. If the catalytic action in the original HTP was due exclusively to Fe³⁺ contamination, its concentration would have been below 1.2×10^{-5} mass-%.

The rate of decomposition of stabilized 30 mass-% H₂O₂ on various materials was studied in 2-N NaOH and 1.95-N H₂SO₄ solutions at temperatures between 295 and 343 K (22 and 70 °C) [451]. These were not catalyst materials, but materials related to electrochemical synthesis of peroxides. A sample size of 0.5 g of the materials in powder form (<75 μm) was dispersed in 50 mL of 30% H₂O₂ in a flask in a thermostat, and the rate of gas evolution was measured volumetrically and entered into Arrhenius plots. The activation energies are summarized in Table 45.

If the pre-exponential factor was plotted against the activation energy, a linear relationship was observed. The rate of decomposition in 1.95-N H₂SO₄ solutions was an order of magnitude slower than in 2-N NaOH. The activation energies for reactions catalyzed by powders were significantly higher than those for solid body catalysts; see also [452].

4.8 Catastrophic Thermal Decomposition of Hydrogen Peroxide

Hydrogen peroxide is a very versatile reagent for many industrial processes, but it is very sensitive to impurities that can catalyze its decomposition violently and cause damage to equipment and personnel.

In investigating an accident, the adiabatic stability of 30% hydrogen peroxide was tested by an accelerating rate calorimeter (ARC) [453]. The measured data were modified by considering of thermal inertia factor of ARC. The results showed that the initial exothermic temperature for 30% hydrogen peroxide is 307.6 K (34.5 °C), with the maximum temperature being 519 K (246 °C), and the time to maximum self-heating rate was 100 min; see also [454–456].

In a critical review of several hydrogen peroxide explosion accidents, investigators sought to establish an evaluation model for its safe storage and transportation [425, 457, 458]. The runaway scenario that can serve as a basis for the assessment of the thermal risk is based on an adiabatic temperature increase and pressure rise of closed or insufficiently vented systems. Both closed and open systems were discussed. The time to adiabatic maximum rate (TMR_{ad}) was presented as the probability of occurrence of the scenario. Two examples both with and without contamination showed that at 293 K (20 °C) the severity of 30% H_2O_2 decomposition is critical, and a small amount of Fe^{3+} (12.7 mg/L) reduced the TMR_{ad} of 30% H_2O_2 by almost a factor of 11.

4.8.1 Chemiluminescence During Liquid-Phase Thermal Decomposition of Hydrogen Peroxide

Decomposition of hydrogen peroxide in water is accompanied by an ultraweak luminescence [459]. The quantum yield was approximately one photon per 10^{14} to 10^{16} transformation acts of hydrogen peroxide. The kinetics of luminescence and its depen-

dence on the reaction of hydrogen peroxide decomposition were investigated, and an attempt was made to identify the elemental reaction responsible for the most intense luminescence (even in the absence of luminol or other organics).

4.9 Stabilizers for Hydrogen Peroxide

We list stabilizers here mainly because they may interfere with some of the intended applications of stabilized HTP in rocket engines, predominantly monopropellant rocket engines. Many stabilizers will clog (“foul”) the catalyst bed or poison the catalyst (*Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide”). We have yet to find a stabilizer that will effectively stabilize the HTP to the same level of long-term storage stability as hydrazine and still not interfere with catalyst operation in a monopropellant engine. There are several types of stabilizers for liquid hydrogen peroxide and its aqueous solutions. One group of stabilizers seems to owe its activity to the complex-forming ability, which serves to sequester heavy metal ions from the solution; in this group, the pyrophosphates, fluorides, cyanides, and various organic substances such as 8-hydroxyquinoline and acetanilide may be mentioned. Another group of stabilizers are suspended colloidal solids, which owe their activity to adsorption powers. Substances such as freshly precipitated alumina and silica, hydrous antimony oxide, and hydrous tin(IV) oxide are effective to varying degrees in increasing the stability of hydrogen peroxide solutions. The degree of stabilization depends upon the nature of the catalyst, pH of the solution, temperature, and the main contaminant(s) present. Thus, the decomposing action of copper ion under certain circumstances is inhibited by tin(IV) oxide and less by pyrophosphate, while the opposite is true for chromium ions. Often, commercial hydrogen peroxide contains more than one type of stabilizer.

Stability is achieved by not just adding a single component but rather a “cocktail” of different chemicals that supplement each other. The primary hydrogen peroxide stabilizer is tin(IV) hydroxide supplied as stannate that forms colloidal stannic acid (hydrated stannic oxide, aq. SnO_2) particles. Normally the tin is added as an alkali metal stannate, such as sodium stannate trihydrate or potassium stannate trihydrate. Unfortunately, positively charged ions, such as calcium, magnesium, and aluminum tend to coagulate the sol and, consequently, remove the tin by settling or filtration. Negatively charged ions such as pyrophosphates and phosphates can be used as peptizing agents to improve the stability of colloidal stannic oxide. Numerous organic phosphonic acids may also be used as stabilizers. Those stabilizers act by chelating metal ions that catalyze or enhance the peroxide decomposition. However, some of these stabilizers undergo chemical changes in peroxide solutions that make them poor chelators for metals, and hence the stabilizing effect is dissipated with time. The phosphonic acids may include those with a nitrogen atom which is capable of being oxidized to an *N*-oxide, such as amino tris(methylenephosphonic acid) (ATMP) and

ethylenediaminetetra(methylenephosphonic acid) (EDTMP), or those not capable of being oxidized, for example 1-hydroxyethyl-1,1-diphosphonic acid (HEDP). In addition to these stabilizers, corrosion inhibitors to prevent hydrogen peroxide attack on metals during extended storage periods in metal tanks complete the recipe. Both nitrates and pyrophosphates play an important role in this respect. Acids are added as buffering agents and to adjust the pH value of the final product.

The catalytic action of dissolved homogeneous catalytic contaminants can be inhibited by the addition of complex-forming stabilizers, such as phosphoric acid, sodium dihydrogen phosphate, 8-oxyquinoline or barbituric acid. Phosphonic or aminophosphonic acids may also be used. Pyrophosphate is a peptizing agent that improves the stability of colloidal stannic oxide and also acts as a corrosion inhibitor [460].

A long list of stabilizers ($\text{Na}_4\text{P}_2\text{O}_7$, Na_3PO_4 , NaH_2PO_4 , H_3PO_4 (85%), H_2SO_4 , HNO_3 , NH_4NO_3 , NaNO_3 , KF , NH_4F , NH_4HF_2 , $\text{Al}(\text{OH})_3$, Al_2O_3 , MgO , SnO_2 , SnO , hexamethylenetetramine), added at concentrations of 100 ppm to 89.4–92% HTP in contact with 99.7% chemically pure soft aluminum coupons or stainless steel coupons was tested for up to 41 days at room temperature [365]. Acidic compounds, except for H_3PO_4 , caused accelerated HTP decomposition. The best results were obtained with sodium dihydrogenphosphate NaH_2PO_4 . Fluorides caused etching and weight loss of both the stainless steel and aluminum coupons. The best performing stabilizers were then tested at 323 K (50 °C) for up to 14 days at two different concentrations. Additions of 100 and 200 ppm of $\text{Na}_4\text{P}_2\text{O}_7$, sodium orthophosphate Na_3PO_4 , sodium dihydrogen phosphate NaH_2PO_4 , phosphoric acid H_3PO_4 , magnesium oxide MgO , or hexamethylenetetramine were evaluated as stabilizers for 89.3% HTP in contact with coupons of CRES-304 or Al52ST in glass flasks during storage at 323 K (50 °C) for up to 14 days, and HTP samples were taken after 1, 7, and 14 days and analyzed for peroxide assay. The best results were obtained with sodium dihydrogen phosphate NaH_2PO_4 in contact with stainless steel and with sodium orthophosphate Na_3PO_4 , in contact with aluminum. Hexamethylenetetramine caused rapid decay of HTP. The higher stabilizer concentration (200 ppm instead of 100 ppm) did not always improve storability and sometimes had the opposite effect. In two separate tests without contact with metal coupons, 89.8% HTP was heated with 100, 500, 1000, 5000, or 10000 ppm sodium orthophosphate Na_3PO_4 to 323 or 373 K (50 or 100 °C) for up to 14 days. The samples with 500 and 1000 ppm phosphate had totally decomposed after only 3 days at 373 K. The samples with 5000 ppm phosphate had totally decomposed after only 7 days at 323 K. The H_2O_2 content of the sample with 100 ppm Na_3PO_4 had dropped to 89.1% H_2O_2 after 14 days at 323 K and to 60.8% H_2O_2 after 14 days at 373 K.

Stabilizers can be dissolved or suspended in the liquid or attached to the walls of the container. Stabilizers cannot change the rate of the slow thermal decomposition of hydrogen peroxide, they can only minimize the adverse effects of contaminants acting as catalysts. The decomposition of H_2O_2 cannot be retarded by increasing the storage pressure either. HTP produced nowadays already has such a high grade of purity that

the addition of stabilizers appears unnecessary. In those cases, stabilizers are added mostly as a precaution against accidental introduction of contaminants at the user's site and after the material has left the manufacturing facility.

There are hundreds of patents with various stabilizer recipes, we list here only a few typical ones. As we explained before, some stabilizers may be tolerated by HTP decomposition catalysts, while others are active catalyst poisons.

A hydrogen peroxide solution having a pH of less than 4.5 was stabilized with about 0.02 to 0.1 g/L of 8-hydroxyquinoline, about 0.2 to 0.6 g/L of a compound selected from the group consisting of tetrasodium pyrophosphate and tetrapotassium pyrophosphate, and about 0.1 to 0.4 g/L of a compound selected from the group consisting of sodium stannate and potassium stannate and phosphoric acid sufficient to furnish the equivalent of about 0.1 to 0.2 g/L of anhydrous phosphoric acid [461].

It was found that the decomposition of HTP in contact with aluminum containing small amounts of heavy metals can be retarded by dissolving 3 mg/L aluminum ion in the form of $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ in 35% H_2O_2 [462]. An aluminum 5652 coupon immersed in 35% H_2O_2 for 3 months caused the H_2O_2 to become contaminated with 10 mg/L of leached aluminum, but the aluminum content of the $\text{Al}(\text{NO}_3)_3$ -treated H_2O_2 remained unchanged. The active oxygen loss of the $\text{Al}(\text{NO}_3)_3$ -treated H_2O_2 was half of that of the untreated H_2O_2 .

4.9.1 Sodium Stannate as Stabilizer

Sodium stannate, 8-hydroxyquinoline ("oxine") and ammonium pyrophosphate/phosphate are the three main stabilizers for H_2O_2 and its aqueous solutions. Sodium stannate is added as $\text{Na}_2\text{SnO}_3 \cdot 3\text{H}_2\text{O}$ but will most likely hydrolyze in the H_2O_2 solution to form a colloidal hydrated tin(IV) oxide.

It has been suggested that this process takes several weeks before the stannate addition becomes effective. This freshly formed colloidal tin(IV) oxide has a large surface area, which absorbs ("scavenges") and deactivates catalytic ions such as Fe^{3+} . The colloid formation is pH-dependent. In 90% H_2O_2 , the stabilizing action of sodium stannate is at its best between pH 3.5 and 6. Some manufacturers will use a buffer to maintain a narrow pH range between 4 and 5. It will take 4–6 h after addition of sodium stannate for the stabilizing action to take effect. This also indicates that this is a solid-state reaction (adsorption) and not an ionic chelating/complexing effect. A $\text{SnO}_2 : \text{Fe}^{3+}$ ratio of 13 to 26 is required for stabilization of H_2O_2 containing more than 0.3 ppm Fe as a contaminant. Other sources suggested that this process (formation of the colloid suspension) takes several weeks before the stannate addition becomes effective. Any sludge that forms at the bottom of the tank after stabilizer addition must be separated from the stabilized HTP before it can be used as a rocket propellant.

Sodium stannate may hydrolyze and form a suspension of colloidal tin(II) oxide. Sodium stannate does not act as a complex former, but bad actors (metal ions) are adsorbed and deactivated on the surface of tin(II) hydroxide [hydrated tin(II) oxide] particles in suspension.

Instead of adding sodium stannate as an aqueous solution to the hydrogen peroxide to be stabilized, it has been proposed to first prepare a more concentrated solution of sodium stannate trihydrate in concentrated hydrogen peroxide and then add this solution to the hydrogen peroxide to be stabilized [463]. After this step, the pH will be adjusted with acid (e.g., citric acid or phosphoric acid).

A colloidal suspension of tin oxide can be produced by operating an electric arc discharge between two tin electrodes submerged under distilled water [464]. In a 24-h test at 373 K (100 °C), the active oxygen loss of a tin-stabilized 30% H_2O_2 sample with 20 ppm tin was an order of magnitude less than that of an untreated sample.

Sodium stannate hydrolyzes completely in 87% concentrated H_2O_2 solution to form a stable lyophobic sol of stannic acid [465, 466]. Precipitation of this sol results by a reduction in the concentration of the potential determining ion (OH^- or O_2H^-) or by the electrostatic adsorption of small quantities of polyvalent cations, e.g., Al^{3+} . In the presence of colloidal stannic acid, the hydrolysis equilibrium of this ion is automatically displaced towards the formation of a stable AlOH^{3+} ion which, by adsorption, neutralizes negative charges on the colloid. Adsorption of aluminum ions is the critical factor governing the stability of stannic acid sols in concentrated hydrogen peroxide solution stored in aluminum tanks [467]. Protection of the sol is afforded by orthophosphate and pyrophosphate ions, which are adsorbed and increase its tolerance for aluminum. Pyrophosphate, in addition, provides an alternative sink for aluminum ions, which are precipitated as aluminum pyrophosphate, AlHP_2O_7 .

The mechanism by which tin hydroxide sols are precipitated by aluminum ions explains the process by which sodium stannate stabilizes commercial H_2O_2 against decomposition catalysts such as the polyvalent ions, Fe^{3+} , Cr^{3+} , and Cu^{2+} . The hydrolysis equilibria of these ions are automatically adjusted to the formation of the stable FeOH^{2+} , CrO^+ , and CuOH^+ ions, respectively, which are strongly adsorbed on the stannic acid colloid and thereby deactivated [468, 469]. These catalytic ions may only be present in minute amounts in non-stabilized commercial hydrogen peroxide (pH ~4.5), mostly in the heterogeneous state. The equilibrium between the heterogeneous and homogeneous phase is disturbed sufficiently to permit the formation of ionic species that are subsequently deactivated by this process.

Stannic acid sols in concentrated hydrogen peroxide differ greatly in appearance and behavior from stannic acid hydrosols in water [470]. In water the sol particles are comparatively large, grow rapidly and are of a feathery appearance, whilst in hydrogen peroxide, the particles are small, compact, and show a distinct but much less pronounced tendency to increase in size with time. This aging process in hydrogen peroxide, which apparently consists of the aggregation of the smaller particles in a polydisperse system, takes place mainly during the first week after

preparation and results in a reduction of approximately 25% in the adsorptive power of the sol.

When tin-stabilized HTP is stored in aluminum containers, part of the tin in the colloid may be displaced by aluminum, causing the colloid to precipitate.

Aluminum strips suspended in 10 to 50 ppm Sn stannate-stabilized 90% H_2O_2 were covered within a few days of immersion with a gray deposit, and there was concern that this loss of stabilizer could cause the HTP to be more susceptible to contaminants. However, when the post-aluminum exposure HTP was challenged by the addition of a small amount of 0.1 ppm. of Fe^{3+} (as the sulfate) to each sample and heated to 323 K (50 °C), but there was sufficient stabilizer remaining even after some of it had been lost due to reaction with aluminum [471].

A decline in the stabilizing activity of sodium stannate induced colloid must be anticipated if the colloiddally suspended tin hydroxide is allowed to coagulate and precipitate [472].

Unstabilized >99% H_2O_2 used for the following tests would decompose in small borosilicate glass vessels at a rate of 0.5 to 1% year⁻¹ at 303 K (30 °C), 10% year⁻¹ at 339 K (66 °C), and 20% year⁻¹ at 373 K (100 °C). Sodium stannate in the form of $\text{Na}_2\text{SnO}_3 \cdot 3\text{H}_2\text{O}$ was added to 99% H_2O_2 at 0.7, 7, and 70 ppm and stability was tested at 303, 339, and 373 K (30, 66, and 100 °C) [307]. A precipitate formed in the 70 ppm solution at pH 3 and 4. The variation of the sodium stannate concentration in pure H_2O_2 was without significant effect on its stability, but lowering the pH had a marked and deleterious effect. Sodium pyrophosphate $\text{Na}_4\text{P}_2\text{O}_7$ was added to 99% H_2O_2 at 1, 10, and 100 ppm and stability was tested at 303, 339, and 373 K (30, 66, and 100 °C) and the pH was adjusted to either 3, 4, or 5. The effect of varying the temperature or the pH was more pronounced than varying the stabilizer concentration. It was concluded that conventional stabilizers, such as sodium stannate, sodium pyrophosphate, or 8-hydroxyquinoline do not improve the stability of 99+% H_2O_2 . The addition of acid will destabilize high-purity H_2O_2 .

Figure 48: Reserve capacity of two different stannate stabilizer concentrations to neutralize an Fe^{3+} ion insult on the stability of 98% HTP. (Reproduced and modified from Huang, Yuan, and Pinsky [402].)

A study of the protective reserve capacity of added sodium stannate as a function of added iron ion contamination showed that stannate at 2.7 ppm Sn provided reserve stability (with no change in measured stability) up to 190 ppb of added Fe (Figure 48) [402].

4.9.2 8-Hydroxyquinoline (Oxine) as Stabilizer

8-Hydroxyquinoline is most often used in the form of its pyrophosphate salt. It is amphoteric and can form cations and anions. If iron is bonded as enolate on the —OH group in the 8 position, it is also coordinated with the neighboring nitrogen atom in the 1 position:

Oxine alone is not very active against iron contamination but in combination with pyrophosphate it constitutes an effective stabilizer. As most organic compounds, oxine is slowly oxidized by H_2O_2 in solution and may not provide the ultimate in long-term stability. The oxidation of oxine by H_2O_2 is catalyzed by Fe^{3+} ions. Addition of pyrophosphate complexes the Fe^{3+} and extends the life of oxine.

Hydrogen peroxide used by the Germans during World War II was usually 85% H_2O_2 and was stabilized with 8-hydroxyquinoline in the form of the pyrophosphate or mixed with sodium pyrophosphate. This organic stabilizer slowly oxidized, and in approximately 6 months it had effectively disappeared. This organic stabilizer is normally considered superior to stannate in protection against iron.

Since 8-hydroxyquinoline is a light fluffy powder and not immediately soluble in H_2O_2 , it tends to float on the surface of the liquid without wetting. This difficulty may be overcome by first dissolving the 8-hydroxyquinoline in aqueous alkali. The pH of the finished stabilized solution will be adjusted before shipping or storing it to compensate for the addition of the alkali.

4.9.3 Sodium Pyrophosphate as Stabilizer

Sodium pyrophosphate $\text{Na}_4\text{P}_2\text{O}_7 \cdot 10\text{H}_2\text{O}$ by itself can stabilize H_2O_2 against iron contamination at concentrations up to 10 ppm Fe^{3+} . Like stannic oxide, it is less protective against copper contamination but still better than stannic oxide in this respect. Sodium dihydrogen phosphate and sodium hypophosphite NaH_2PO_2 is a less active stabilizer than sodium pyrophosphate.

4.9.4 Other Stabilizers and Combinations of Stabilizers

Combinations of stabilizers have been tested, and some combinations may exhibit benefactory synergism, where the stabilizing effect of the combination is better than the sum of that of the ingredients by themselves.

Passivation of container walls, in particular in aluminum containers, is a valuable step in minimizing storage stability problems with HTP. Cleaning and passivation methods are discussed in Section 5.3.4.

If a runaway decomposition of a hydrogen peroxide storage tank is imminent, and the contents cannot be drained and diluted fast enough, it has been suggested to add one part of 85% phosphoric acid solution to 100 parts of hydrogen peroxide [473].

A tin pyrophosphate formed by reaction of tin metal with phosphoric acid at 573 K (300 °C) for 1 h is a useful stabilizer.

A three-way stabilizer can be prepared by first preparing a solution of 0.1% $\text{Na}_2\text{Sn}(\text{OH})_6$, allowing it to age for 5 days, adding 0.5% 1,2-diaminocyclohexane-*N,N,N',N'*-tetraacetic acid and 1.1% $\text{Na}_4\text{P}_2\text{O}_7$ to the stannate solution, adjust the pH to 3.1 and using 1 part this stabilizer solution for every 100 parts of 35% H_2O_2 [474]. Standard stability tests at 373 K (100 °C) showed the thus stabilized H_2O_2 to lose less than 0.4% per 24 h.

Magnesium in strongly alkaline (pH > 9) solutions is capable of masking iron and retard the catalytic activity of colloidal iron hydroxides that would have formed in the absence of magnesium [475].

4.9.5 Stabilizers Acting as Catalyst Poisons

The most comprehensive study on the effect of stabilizers as catalyst poisons for hydrogen peroxide catalytic decomposition on a silver catalyst in a reactor with and without various stabilizers was conducted by the Naval Research Laboratory in 1958 [476]. A very high purity, unstabilized hydrogen peroxide that had been purified by a fractional freezing process served as the reference propellant. A 2-cm length of 20-mil pure silver wire immersed in 50 mL of HTP served as catalyst in a constant volume reactor, and the oxygen evolved was measured in a wet test meter. Only a few studies have illustrated the rate of silver loss during the decomposition of HTP as clearly as shown in this report. The small 2-cm length of silver wire lost 5 mg of silver, while the decomposition of (the slowly diluting) HTP generated 20 liters of gas. The effect of HTP concentration on the rate of silver loss was opposite to what would be expected: The initial rate of silver loss was faster in 90% HTP than in 99% HTP (although the maximum rates were similar). Also, the effect of temperature on the rate of silver loss was opposite to what would be expected: The initial rate of silver loss was faster at 293 K (20 °C) than at 358 K (85 °C). One explanation offered for this observation was that at the higher HTP sample temperature, the wire is enveloped by a cloud of gas (film boiling), while at lower temperatures the metal is in contact with the corrosive liquid (nucleate boiling). The rate of HTP decomposition and silver catalyst loss were

dependent on the concentration of stannate, phosphate, and aluminum ion. The effect of tin was dependent on aging, such that the effect was negligible one day after it was first added but became more pronounced with time. The increased silver loss due to the presence of aluminum was moderate. When phosphate was added to HTP in increments, the activity first increased. With concentrations above 2 mg/L, the inhibiting action masked the initial increase. Phosphate sharply increased the amount of silver that dissolved in the decomposing HTP. The catalyst activity was reduced by a factor of 50 when 4 mg/L phosphate was added to the propellant. Addition of aluminum ion or adjusting the pH was ineffective in mitigating the adverse effect of phosphate. Addition of lithium, magnesium, calcium, or barium cations had no effect on the rate of decomposition or the rate of silver loss. Sulfate or nitrate did not alter the activity of silver catalyst in the laboratory studies, but sulfate deposits would clog the rocket engine reactor.

Catalyst pack failures for heterogeneous systems have been reported with phosphate levels of only 0.5 ppm. Apparently, a phosphate level of only 15 ppm causes instant failure of the catalyst; see also [477].

4.10 Catalytic Decomposition of Hydrogen Peroxide

This chapter deals with the unwanted, slow decomposition of liquid H_2O_2 during storage as well the intentional decomposition of HTP achieved by bringing it into contact with catalysts. These catalysts can be heterogeneous, requiring surface contact between the liquid and the solid, or they can be homogeneous substances that are soluble in H_2O_2 or in the fuels brought into contact therewith.

All academic studies on the activity and durability of H_2O_2 decomposition catalysts are summarized here in *Encyclopedia of Oxidizers*, where chemists are likely to find the information they are looking for. The other information in *Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide Monopropellants”, is an engineer’s approach to the task of selecting flightworthy catalysts for engine designs on the drawing board and on the static rocket test stand. There is some overlap between these two sections, so if the information a reader is looking for cannot be found here, it is possible that they may find it in *Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide Monopropellants”.

One of the most complete summary reviews of catalysts for the decomposition of hydrogen peroxide in rocket engines was published in [478]. A thorough compilation of references like the one printed in that paper will make several of the following sections in this chapter unnecessary.

4.10.1 Reaction Mechanisms of Catalytic H₂O₂ Decomposition Reactions

A good correlation between the H₂O₂ decomposition activity and the δ -oxygen non-stoichiometries of non-stoichiometric doped metal oxides was found, especially for lanthanum perovskites. Hence, oxygen vacancies have been suggested to participate in the reaction. Various decomposition mechanisms have been suggested in the literature for the decomposition of H₂O₂ on transition metal (Me) oxide-based catalysts, which involve ions, free electrons, and free radicals. Me could be a metal like manganese or iron, which readily change states of oxidation. These mechanisms can be classified into the following three mechanisms (I), (II), and (III), where mechanism (III) involves a dopant metal:

The mechanisms (I) and (II) describe the decomposition on pure metal oxides and have some steps in common: **(1)** the initial surface oxidation or reduction of H_2O_2 molecules, and **(2)** the surface facilitation of the necessary electron mobilization to generate free radicals.

The mechanism (III) describes the decomposition on composite or doped or ternary metal oxide catalysts, also involving the steps **(1)** and **(2)**, and accounts explicitly for the chain reaction nature of the decomposition reaction propagation [479].

Many of the studies on catalysts for decomposition of hydrogen peroxide were carried out in dilute solutions, so as to avoid runaway situations and maybe even maintain isothermal conditions. Such studies in dilute solution may be only of limited value to a rocket designer, but they help us develop more active catalysts for the decomposition of hydrogen peroxide and other monopropellants in higher concentrations.

4.10.2 Catalysts for H_2O_2 Decomposition

4.10.2.1 Homogeneous Catalysts for Hydrogen Peroxide Decomposition

Homogeneous catalysts are discussed here first, not necessarily because they are the most important mode of H_2O_2 decomposition initiation, but because historically this appears to be the first method that was used practically. This method is rarely used in today's H_2O_2 energy systems, and this chapter is relatively short, much shorter than the subsequent chapter on heterogeneous catalysts for the composition of H_2O_2 . One main disadvantage of homogeneous catalyst injection is that for monopropellants, a second liquid must be stored in a separate tank, or the catalyst has to be soluble in a fuel in order to hypergolize it as soon as it comes into contact with H_2O_2 in a bipropellant engine. The need for pressurizing the second tank and metering the liquid catalyst in carefully controlled proportions in relation to the variable main H_2O_2 flow adds to the complexity of the system. Many aqueous catalyst solutions freeze or crystallize from a saturated solution as soon as the ambient temperature drops to cold season conditions. A potential advantage of homogeneous catalysts for decomposition HTP is that they are insensitive to stabilizers in the HTP that could otherwise foul heterogeneous packed catalyst beds.

A very comprehensive review of the reactions of hydrogen peroxide with catalysts in aqueous solutions was published in 1952 and included 132 references [480]. It includes detailed discussions of reactions of H_2O_2 with Fe^{2+} and Fe^{3+} ions, ferrocyanide and ferricyanide ions, copper compounds, Cu^{2+} ions, copper complexes, permanganate, chromate, molybdate, and tungstate.

Sodium iodide solutions were tested by FMC and the US Navy during the years after WWII for an intended torpedo propulsion system but were later replaced by silver screen catalysts. Operating times up to 10 h were demonstrated with a sodium iodide/90% HTP in comparison to 0.014-in. diameter silver wire woven into wire mesh in a H_2O_2 system.

The homogeneous catalysts used most often were aqueous solutions of alkali metal and alkaline earth metal permanganates: KMnO_4 , NaMnO_4 , $\text{Ca}(\text{MnO}_4)_2$ [365, 481, 482]. In the steam generator of the German A-4 rocket, additional decomposition of H_2O_2 was achieved by lining the reactor with bricks made of $\text{Ca}(\text{MnO}_4)_2$.

The solubilities of permanganate salts in water increase in the order $\text{KMnO}_4 < \text{NaMnO}_4 < \text{Ca}(\text{MnO}_4)_2$. Attempts to add the homogeneous permanganate catalysts to non-hypergolic fuels (alcohols, amines) as a means of hypergolization failed in most cases because the permanganate oxidizes the organic compounds. Other manganese compounds have also been tested for this purpose. As part of the “green” propellant effort in the 1990s numerous fuel-soluble catalysts were tested to initiate the decomposition of H_2O_2 in contact with otherwise non-hypergolic fuels. Although these are truly hypergolic propellants that should be discussed in another volume of this series, we summarize some of the homogeneous catalysts here regardless of whether they are used for initiating the decomposition of H_2O_2 by itself or in the presence of a fuel where the fuel is added to increase the specific impulse (Table 46).

Table 46: Fuel-soluble homogeneous catalysts for initiation of H_2O_2 decomposition or hypergolization of fuels.

Catalyst compound name	Chemical formula	Fuel	Catalyst concentration used, mass-%	References
Sodium nitroprusside = di-sodium pentacyano nitroso ferrate(II) dihydrate	$\text{Na}_2[\text{Fe}(\text{CN})_5\text{NO}] \cdot 2\text{H}_2\text{O}$	85% Hydrazine hydrate	1.07 g/L	[483, 484]
Iron(II) β -naphthalene sulfonate trihydrate “Naphferrol”	$\text{Fe}(\text{C}_{10}\text{H}_7\text{SO}_3)_2 \cdot 3\text{H}_2\text{O}$	Methanol	200 g/L	[483]

If the methanol/naphferrol solution is allowed to stand in contact with air, the salt will autoxidize, and the insoluble Fe(III) salt will precipitate from the solution.

Pentacyanonitrosoferrates are not suitable as fuel-dissolved catalysts for long-term storage since they may react with hydrazine or hydrazine hydrate used as fuels [484].

Two types of very small thrust chamber prototypes based on the homogeneously catalytic decomposition of hydrogen peroxide by an aqueous solution of iron(II) chloride have been fabricated by precision machining and silicon etching process [485]. One prototype had a conical nozzle with a throat diameter of 0.3 mm, while the other has a planar nozzle with a rectangular throat section of 0.04 mm $\times$ 0.2 mm. Controlled by two miniature electromagnetic valves, the thruster system could work in either continuous or pulse mode. In preliminary experiments on these prototypes, a smallest impulse per controlling pulse of less than 80 $\mu\text{N s}$ was obtained.

Ions of water-soluble permanganate catalysts probably do not act as such, but a reaction between permanganate and peroxide at high pH or a reaction between manganese(II) ion and alkali forms finely divided manganese dioxide, which then acts as a catalyst [486, 487]. No catalysis occurred until the solution was saturated with manganese(II) hydroxide. By using radioactive tracer methods, it was shown that no exchange takes place between manganese(II) ion and manganese(IV) dioxide in aqueous suspensions. However, as soon as hydrogen peroxide is added, a complete exchange of manganese takes place as both manganese(II) ion and manganese(IV) dioxide react with the hydrogen peroxide. Similar observations were made with mixtures of cobalt(II) ion and cobalt(III) hydroxide [488].

Some liquid catalysts have a nasty tendency to precipitate at the outlet to the injector, clogging the orifices and, thus, limiting their use for multiple engine restarts. Experiments have been carried out with several liquid catalysts, from which the rate of reaction and the tendency to form precipitates were compared against the benchmark catalytic agent, sodium permanganate [489–492]. The concentration of highly stabilized HTP used in these tests was between 81 and 86% H_2O_2 . It was found that, although exhibiting a reduced tendency to form precipitates, none of the candidate agents considered matched the reaction rate of sodium permanganate. Catalysts were injected with a syringe into 10–80% H_2O_2 in a closed vessel reactor, and the rate of oxygen evolution was measured as indication of catalyst activity. Sodium iodide gave a sustained decomposition but had a long startup delay. Iron(II) chloride tetrahydrate had no ignition delay and was capable of producing useful decomposition temperatures. After completing the closed vessel reactor tests, the candidate liquids were injected together with 83% H_2O_2 in a simple 100-N monopropellant thruster simulator, and the temperatures at various distances from the impingement point were measured as a function of time. The reactor was intended as the ignition source for a bipropellant engine with downstream injection of hydrocarbon fuels (*Encyclopedia of Non-hypergolic Bipropellant Combinations*, the chapter “Hydrogen Peroxide”).

Hydrogen peroxide (in much lower concentrations than those used in rockets) can also be decomposed by many organic enzymes, e.g., catalase, liver extract, saliva, or yeast. An enzyme in saliva causes the decomposition of dilute H_2O_2 solutions used as a mouthwash. These materials are very effective in decomposing dilute hydrogen peroxide but are sometimes destroyed by concentrated H_2O_2 before they can cause continued H_2O_2 decomposition.

The bombardier beetle activates a defense mechanism by mixing a solution containing hydrogen peroxide and hydroquinones with an enzyme solution in a bladder, causing instant decomposition of the mixture and rapid, oscillating ejection of the hot reacting mixture in a well-aimed jet to ward off potential predators [493], Figure 49.

Figure 49: Bombardier beetle discharging a jet of hydrogen peroxide / hydroquinone reaction products. (From [493])

4.10.2.2 Laboratory Test Methods for Catalysts with Liquid Hydrogen Peroxide

Before monopropellant decomposition catalysts advance to the level of rocket engine testing at high pressures, they are usually tested at atmospheric pressure in the laboratory. A variety of catalyst tests methods has been described in the literature, which have been used for all types of monopropellants, including hydrazine, hydrogen peroxide, and hydroxylammonium nitrate-based monopropellants (*Encyclopedia of Monopropellants*). Many of these machines have been patterned after hypergolic ignition delay test apparatus designs. The machines are usually readily converted from the use of one type of monopropellant to another.

There are several test methods for the evaluation of catalysts for the decomposition of hydrogen peroxide. Some are as simple as an open-air ceramic spot plate (or ceramic crucible) test with hydrogen peroxide administered by hand from an eye dropper, others are more sophisticated with temperature and pressure instrumentation. This most common test method is a “drop test”, where a drop of liquid propellant is added to a catalyst sample in a crucible, and the reaction is monitored with thermocouples or observed with high-speed video recording. The key parameter is the ignition delay from the moment of drop impingement to the first sign of an exothermic reaction.

Other catalyst test machines have immersed a single catalyst granule in a large excess of liquid (with agitation to enhance mass transfer) and measured the rate of gas evolution with a flow meter or a gasometer.

The best reproducible results are obtained with constant volume reactors instrumented for high-speed temperature and pressure recordings independent of operator skills in adding a droplet to a grain of catalyst.

Closed Bomb/Constant Volume Reactors

Silver granules (10–20 mesh), 4% Ag/ Al_2O_3 , and 1.6% Mn manganese oxide/ Al_2O_3 catalysts were tested with 30 and 50 mass-% hydrogen peroxide in a 170-mL constant vol-

ume instrumented batch reactor operating between vacuum and 2 bar [494–496]. The 100–200 mg catalyst sample could be repeatedly exposed to 10–100 μL propellant injected from a syringe. Between multiple tests, the exhaust products would be pumped off to vacuum. The reactor could simulate pulse mode operation of a monopropellant rocket engine but not the steady-state operating mode. Catalytic decomposition of 30 and 50 mass-% hydrogen peroxide was compared to that of anhydrous hydrazine (Ir/ Al_2O_3 catalysts) and XM46 (Pt/ Al_2O_3 catalysts) in the same reactor, based on the comparison of pressure, pressure rise rate, and temperature. In the presence of the silver catalyst, 50-% H_2O_2 decomposed starting at room temperature. For H_2O_2 the reactor did not need to be preheated to 403 K (130 °C) as with XM46. The ignition delay was 0.3 s for 50% H_2O_2 at 293 K (20 °C). The supported silver/ Al_2O_3 catalyst noticeably lost activity after only three injections.

A closed bomb reactor was used to assess the performance of catalysts for decomposition of high concentration hydrogen peroxide [497]. The catalysts had different chemical and geometrical characteristics and consisted of wire screens, metal foams, and coated or impregnated ceramic pellets. The apparatus was designed to measure the rate at which gas is evolved when hydrogen peroxide comes into contact with a catalytic material. Initial work used ceramic-pellet based carriers. The apparatus allowed a small quantity (typically 3 mL) of 87.5% hydrogen peroxide to be injected rapidly into a reaction chamber, which was allowed to exhaust into a sealed vessel. The aim was to identify the time delay between the introduction of the HTP and the end of the decomposition reaction, and thereby assess the catalyst activity. This was achieved mainly by monitoring the pressure and temperature rise in the sealed vessel. Catalysts tested included 0.5 mass-% Pd on Al_2O_3 , 0.5 mass-% Ru on Al_2O_3 , 0.5 mass-% Pt on Al_2O_3 , and 1 mass-% Pt on Al_2O_3 . The catalyst carriers for manganese oxide impregnation were γ -alumina with a surface area of 200–260 m^2/g and zirconia with a surface area of 95 m^2/g . The catalyst that achieved the highest ranking was a manganese oxide/zirconia catalyst.

Dynamic Flow Reactors

Different types of cellular ceramic-based catalysts for 87.5% hydrogen-peroxide decomposition at miniature scale with nominal mass flows of 0.3 g/s were tested in a flow reactor configuration similar to a propulsion application [498]. The test matrix included honeycomb monoliths with different channel geometries, densities, lengths, different carrier materials, and washcoating procedures, as well as different types of catalysts such as pellets and foams. There were 39 catalyst configurations with a total of 121 catalysts that were experimentally investigated based on their transient and stationary performance at design mass-flow levels of 0.3 g/s and a bed loading of 2.5 $\text{kg m}^{-2} \text{s}^{-1}$. The duration of the tests was typically 200 s to achieve steady-state operating conditions.

Gravimetric, Open Venting Methods

While the constant volume reactor measures the initial startup performance of a catalyst, the gravimetric open venting method is designed to assess lifetime [499]. This is achieved by measuring the change in mass of a 30% hydrogen peroxide solution as its decomposition is being catalyzed. A fixed volume (100 mL) of 30% hydrogen peroxide is held in a beaker placed on a digital readout balance. At time zero the catalyst with a known surface area is added into the beaker. As the 30% peroxide solution decomposes, oxygen and some water vapor are released leading to a reduction in mass, which is measured in 1-s intervals. The experiment is stopped after a fixed time or when the mass change is below 1% of the remaining mass. At this time, the pellets are removed, and the solution replaced with a fresh 100 mL of 30% hydrogen peroxide solution. The experiment is repeated until the catalyst is exhausted. The catalyst performance is judged on two parameters: the rate of mass change and the number of full cycles required to exhaust the catalyst.

Volumetric, Open Venting Methods

The easiest method to measure activity of catalysts is to place a small (20 mg) catalyst sample in a test tube in a glass vessel with multiple ports for injection of the liquid H_2O_2 from a pipette, thermocouples measuring liquid and gas temperature, a pressure relief valve, and the vent gas port through which gases and vapors leaving the vessel enter a condenser where steam and unreacted H_2O_2 are condensed out, and the non-condensable gases are metered through a flow meter. The quantity of H_2O_2 injected is selected such that it may take 60–100 s to consume all the propellant. This method has been used for characterizing candidate catalysts before advancing to reactor testing in a rocket engine [500]. Two types of samples were tested: powders and metal wires. Of the four powder catalyst samples tested, Mn_2O_3 was the most active catalyst powder followed by silver, MnO_2 , and MnO in order of decreasing activity. Four different 0.1 mm diameter metal wires of 150 mm length (gold, platinum, palladium, silver) were coiled to form spirals with a diameter of 5 mm and immersed in 10 g of H_2O_2 . In this experiment, silver showed the best activity and gold the worst, with platinum second and palladium third. However, in some experiments, the silver wire dissolved with time, indicating that its life as a catalyst could be limited.

Other Test Methods

One can also study the phenomena occurring at the H_2O_2 /catalyst interface by visual observation. (From a safe distance with a telescope). When observing H_2O_2 on the surface of a metallic catalyst (a silver tube with the potential of temperature conditioning by flowthrough water) with a telemicroscope, the visual appearance reminds one of nucleate or film boiling of a liquid on a hot surface [501]. The heat of decomposition of H_2O_2 is released in a thin layer on the surface of the catalyst. Decomposition of $\leq 45\%$ H_2O_2 releases individual bubbles, and with $\geq 60\%$ H_2O_2 the catalyst is enveloped in a steam bubble (a vapor barrier) and no longer in contact with the liquid. The maxi-

imum heat flux is achieved at 47% H_2O_2 , which is at the upper limit of nucleate boiling. If one plots the heat flux as a function of the temperature difference between the surface and the liquid, the maximum is at a ΔT of 55 K (100 °F) and occurs with 47% H_2O_2 . The heat transfer through the steam layer is very slow, like that in film-boiling heat transfer, so that the catalyst can become very hot. A new silver surface had to be in contact with HTP for 5–10 min before a constant rate of gas evolution was attained. In the presence of a large excess of liquid, the temperature of the silver tube never exceeded the boiling point of HTP. Some of the silver eroded and was carried away in the flowing H_2O_2 in the form of small particles, and the finely divided silver particles caused additional decomposition away from the surface.

Catalyst immersion tests at Purdue University totally immersed the 1-inch cubes of catalyst-coated Celcor monoliths in hydrogen peroxide with a concentration of <10 mass-% H_2O_2 and allowed it to react in a controlled environment [502]. A thermocouple was used to collect temperature data. At set time intervals, samples of the hydrogen peroxide were taken and examined in the refractometer. This allowed for the qualitative determination catalyst activity.

The only apparatus capable of testing hydrogen peroxide decomposition catalysts at elevated pressures is the apparatus designed at Purdue University. This catalyst immersion test apparatus simulated rocket chamber conditions more closely than a spot plate or Pino tester and consisted of a 5 cm diameter ID $\times$ 20 cm length, 25-mm wall thickness CRES-304 chamber with a propellant fill port and a vent orifice, containing 100 to 250 mL HTP, carrying five thermocouples and a pressure transducer and a movable catalyst holder on a rod that could be moved up and down by a pneumatically actuated piston [503, 504]. The lower liquid limit (100 mL) was to ensure that the catalyst would be fully wetted when immersed while the upper limit was dictated by the position of the fill valve. Initial testing was conducted with hydrogen peroxide and silver screen catalyst samples. The bottom of the chamber had an O-ring seal through which the rod slides up and down. At the beginning of the test, the catalyst mounted at the tip of the rod was in the vapor phase. The catalyst rod/holder was translated in the vertical direction by use of air pressure and a three-way pressure-loaded solenoid valve. Shop air was used as the pressure source for the air cylinder. When toggled, the valve acted to load one end of the air cylinder, while relieving the other end, raising or lowering the catalyst holder in the process. The valve was controlled remotely. Reaction started when the rod was moved down, and the catalyst was completely immersed in the liquid. The nominal operating pressure was <6.2 MPa (<900 psia). With an active catalyst, such as 18-mesh pure silver screen, a chamber pressure of 6 MPa was achieved within 5 s. Higher chamber pressures could be achieved by using smaller vent orifices. The temperature and pressure traces of the test (Figure 50 bottom and top) usually showed two phases, which differed in activity.

The slow Phase I continued until the liquid boiling point was reached. At atmospheric pressure 90% H_2O_2 has a boiling point of 414.4 K (286.2 °F). During testing, a dramatic change in flow attributed to boiling occurred at ~403 K (~265 °F). The low-

Figure 50: Pressure and temperature traces from a hydrogen peroxide/catalyst immersion test. (Reproduced and modified from [504].)

ered boiling temperature is associated with the lowered concentration due to H_2O condensation. Once the boiling point was reached, Phase II started, and the pressure and temperature inside the vessel rose rapidly, which typically took ~ 100 s. While the particular pressures and temperatures varied depending on the test parameters, the two-phase region behavior was exhibited in almost every test. The duration of Phase II reaction was limited by the amount of peroxide available. A constant pressure was not achieved in Phase II. The pressure rise simply ceased after all H_2O_2 had been consumed.

4.10.2.3 Heterogeneous Catalysts for Hydrogen Peroxide Decomposition

Heterogeneous catalysts for the decomposition of hydrogen peroxide (and most other monopropellants) can be elemental metals in various forms (wire, mesh, foil, pellets, spheres), active metals supported on ceramic carriers, metals cosintered or copressed with metal oxides (“cermets”), or metal oxides. Catalyst researchers have crisscrossed the periodic table of elements in search for metals and metal compounds that are active as catalysts for decomposition of HTP in rocket engines. This effort was very similar to the search for hydrazine decomposition catalysts. For hydrogen peroxide, initial efforts essentially very quickly boiled down to two heterogeneous catalysts: metallic silver and manganese dioxide.

It is unfortunate that many of the publications dealing with catalysts for the decomposition of hydrogen peroxide did not state the level and type of stabilizers in the hydrogen peroxide that they used for the catalyst activity experiments. Stabilizers may act as catalyst poisons. Only very few experimenters were smart enough to test their catalysts side-by-side with both a stabilizer-free hydrogen peroxide and a stabilized type of hydrogen peroxide.

Many of the studies of heterogeneous catalysts for H_2O_2 decomposition referenced here worked with relatively dilute solutions, too dilute to be of any interest as a rocket propellant. However, some of the kinetics derived from such studies apply to hydrogen peroxide decomposition in higher concentration solutions as well. Some of the studies dealt with premature H_2O_2 decomposition at the electrodes of fuel cells, which limits the useful life and energy storage capacity of fuel cells but is only of marginal interest for a rocket application. A short overview of catalyst design for hydrogen peroxide decomposition was published in 1961 [505].

FMC developed hydrogen peroxide decomposition catalysts under a series of US Air Force contracts in the 1960s and in support of laboratory work has done an exhaustive literature survey covering the literature between 1945 and 1965 [506]. This is a very useful introduction into this topic and should have been updated periodically. The main source of information was *Chemical Abstracts*. The literature survey with 394 references is nicely arranged by grouping the metals in the same order as in the periodic table of elements. That helps to bring out similarities in the vertical groups. The survey showed that silver and platinum were the most extensively investigated catalysts. Other major catalysts were palladium, copper, iron, cobalt, manganese, and their compounds. Various methods have been proposed to increase catalytic activity by additives that promote the parent activity of elements or compounds. Samarium nitrate-treated silver, cobalt-manganese oxide mixtures, ruthenium and its compounds, and silver-gold alloys were the most active catalysts reported; see also [507, 508].

For the selection of catalysts, it was proposed that the dependence of the adsorption γ of a standard series of organic substances on their ionization potentials (I) on the adsorbents be obtained first [509]. It was shown for the example of catalytic decomposition of hydrogen peroxide that adsorbents for which the maximum on the $\gamma =$

$f(I)$ curve coincides with the ionization potential of the starting compound undergoing transformation are active catalysts.

Activated charcoal would not be a good catalyst support for HTP applications in a rocket engine, because it would burn away like a hybrid fuel grain, but some grades of carbon black will catalyze the decomposition of hydrogen peroxide [510, 511]. Carbon-black filled elastomers (typical black rubber) or graphite bearings must be avoided if they come into contact with hydrogen peroxide liquid or vapor.

It is interesting to note that dissolved silver salts do not have a catalytic effect. As a solvent 90% H_2O_2 can be saturated with silver nitrate, and the solution remains stable. It has been noted that silver metal and silver(I) oxide dissolve somewhat in H_2O_2 , and that the decomposition ceases as soon as the solid catalyst is removed. The remaining leached silver ions have no effect on the H_2O_2 decomposition if the solution remains acidic or neutral. As soon as a trace of alkali is added and the pH is raised, a brown precipitate ($AgOH$ or AgO_2H) forms that is a very active catalyst.

This is only an incomplete sampling of the literature on the catalytic decomposition of hydrogen peroxide. There are so many papers on multi-element comparative evaluation of heterogeneous catalysts for decomposition of hydrogen peroxide that we had to arrange them in chronological order. Following the chronological multi-element list, there are sections dealing with only one specific element or its oxide(s) as H_2O_2 decomposition catalysts.

4.10.2.4 Supported Metal and Metal Oxide Catalysts

Platinum deposited on molecular sieves or zeolites may be suitable for selective oxidations of organic compounds with H_2O_2 in dilute solutions (such as the epoxidation of alkenes), but they do not stand up to the high temperatures in a rocket engine [512, 513].

Supported catalysts containing the oxides of silver, ruthenium, manganese, lead, vanadium, or chromium on a granular alumina or alumina-silica carrier were prepared and evaluated for their hydrogen peroxide decomposition activity in a stirred batch reactor [514–517]. Uniform active metal loading (g-atom per unit surface area) was to allow comparison of the different metals (or their oxides). Soluble salts of the metals [$AgNO_3$, $RuCl_3$, $Mn(NO_3)_2$, $KMnO_4$, NH_4VO_3 or $(NH_4)_2CrO_4$] were dissolved in water to obtain solutions at a defined concentration of 0.96 g-atom metal per liter. The carrier granules were soaked only once in half their bulk volume of solution for 4 h and then dried and weighed to determine the weight gain of undecomposed salt. The weight gain depended on the affinity of the carrier for the metal ions. Active metal oxide loading varied accordingly. The dried catalyst was calcined in air for 15 h and weighed to determine the metal oxide loading. In addition, the active metal loading was determined by extracting the catalyst with either concentrated hydrochloric acid or *aqua regia* for 24 h and analyzing the metal content in the extract by ICP. The carriers evaluated included four molecular sieves, five aluminas, three alumina/silicas with three different $Al_2O_3 : SiO_2$ ratios, and silica. The H_2O_2 decomposition activity

was determined in a batch reactor, which was a 50-mL spherical glass flask containing 20 mL of 70% stabilized hydrogen peroxide (FMC/SC grade). This reactor reminds us of the one used by the Shell Development Company in 1962 during the early development phase of a hydrazine decomposition catalyst that was later named Shell 405, and this historical event was the most successful catalyst development for rocket applications in a long time. FMC/SC 70 contained 63.9 mass-% H_2O_2 , 0.68 mg/L P, 2.01 mg/L Na, and 0.67 mg/L Sn. The solution was stirred with a magnetic stirrer and a glass-encapsulated thermocouple was inserted into the solution, and the time to max temperature was recorded. At time $t = 0$, a precise weight of catalyst was dropped into the hydrogen peroxide solution. Forty μL aliquots were withdrawn from the batch at defined time intervals, which were then analyzed for remaining H_2O_2 content by refractive index. In the immersion batch reactor, the most active catalysts were a ruthenium oxide/ Al_2O_3 catalyst, a commercial 1% Pt/ Al_2O_3 , and calcined potassium permanganate on mol sieve. It was learned that tetravalent manganese is more active than trivalent manganese as a catalytic agent, that base-promoted manganese exhibits lower weight loss during calcination than manganese alone, and that neutral silver is more catalytically active than silver oxide. It was planned to test the most active catalysts in a flow reactor that would more closely represent actual rocket engine operating conditions than a batch reactor. Catalysts based on molecular sieves may be suitable for selective oxidations of organic compounds with H_2O_2 in dilute solutions (such as the epoxidation of alkenes), but they do not stand up to the high temperature in a rocket engine.

The preparation of supported iridium catalysts for decomposition of hydrogen peroxide is described in [518]. In a method for preparing this hydrogen peroxide decomposition catalyst, the porous particulate carrier is impregnated with an organic solvent solution of H_2IrCl_6 , dried, calcined, and reduced. This catalyst is similar to Shell 405.

The oxides of silver, ruthenium, manganese, lead, vanadium, and chromium deposited on a commercially available molecular sieve, alumina, alumina/silica, and silica carriers were evaluated for the decomposition of rocket-grade HTP [519]. Soluble salts of the above cations were dissolved in water to obtain solutions at a defined metals concentration of 0.96 mol/L. Calcinations were performed in a furnace by roasting in air at above the known decomposition temperatures for 15 h. The finished catalysts were then tested in a batch reactor consisting of a 50-mL spherical glass flask containing 20 mL of 70% stabilized hydrogen peroxide (FMC/SC grade). The solution was stirred at a defined angular velocity with a magnetic stirrer and a glass-encapsulated thermocouple was inserted into the solution. At time $t = 0$, a precise weight of catalyst was dropped into the hydrogen peroxide solution. Forty microliter aliquots were withdrawn from the batch at defined time intervals, which were then analyzed by refractive index. A temperature record was also obtained for each experimental run. By plotting $-\ln [C_t/C_0]$ versus time, and knowing the catalyst molar metal loading, k' , the catalytic rate constant, was obtained for a variety of catalyst types. The rate constant was then normalized to the number of active catalyst metal atoms loaded onto the carriers

to generate k' . The most active catalysts were those containing ruthenium oxide and manganese oxides obtained by decomposition of potassium permanganate. Tetravalent manganese was found to be more active than trivalent manganese, and neutral silver was more catalytically active than silver oxide.

An assortment of metallic and supported catalysts for an 85% HTP decomposition chamber that was intended as an igniter for a hybrid rocket was investigated at the University of Surrey [520]. The effort was centered on a hydrogen peroxide hybrid rocket to be used as satellite kick stage. During Phase 1, between August 1994 and February 1995, a total of seven different catalyst pack configurations were tested:

- Type-1: maximum density silver-plated nickel gauze
- Type-2: maximum surface area silver-plated nickel gauze
- Type-2A: Type-2 catalyst, sintered for 30 min at 800 °C
- Type-3: KMnO_4 crystals
- Type-4: LCH 212
- Type-4A: LCH 212 plus Shell 405 in upper bed
- Type-5: silver-plated gauze provided by the US Air Force Academy
- Type-7: stacks of pure silver screen and stacks of very rough silver plated on a nickel screen

Note: What Surrey calls “LCH 212” is actually LCH-202 (from the author’s laboratory) that was salvaged along with Shell 405 catalyst from surplus Chevaline Peace Courage post-boost propulsion systems built by Rocket Research Company (RRC) for Bell Aerospace (Buffalo, NY) and Royal Ordnance in the UK that were cut open and the catalyst removed and diverted for other purposes. They also used it for N_2O decomposition.

The overall performance with the Type-4 catalyst was fair. Startup was relatively slow (accounting for the low average T_c) but the overall performance was consistent, and no wet starts were observed. On all runs, temperatures consistently reached nearly 873 K (600 °C). After the last test, the Type-4 catalyst was examined to reveal that the glossy black finish on the pellets had taken on a white discoloration over much of the surface. This was most likely due to oxidation of the iridium by the peroxide. Because of this rapid oxidation, LCH and Shell 405 had to be ruled out for long-term space applications. However, because of its consistent performance, a modified catalyst pack, Type-4A using both LCH and Shell was used for a hybrid ignition test. Nine 30-s tests and one 20-s test were conducted with the Type-7 catalyst with good results.

Five metallic and five metal oxide catalysts supported on 18–24 mesh granular alumina were prepared and evaluated by measuring the rate of gas evolution of a 30-mg catalyst sample in 2 mL of 80-% H_2O_2 [521]. The catalysts with various molar ratios were prepared by impregnating the alumina support with a metal salt solution. The impregnated catalysts were dried at 373–393 K (100–120 °C) for 12 h, and then calcined in a muffle furnace in air at 673–1073 K (400–800 °C) for 4 h. The total loading of the metal oxides was 3–25 mass-%. The activity of the metal catalysts in decreas-

ing order was $\text{Ir} > \text{Ru} > \text{Ag} > \text{Pt} > \text{Pd}$ and the activity sequence of metal oxide catalysts was $\text{MnO}_x > \text{CoO}_y > \text{FeO}_y > \text{PbO}$. MnO_x was the most active catalyst among these metal oxides. When doped with other elements, the activity of MnO_x could be enhanced. A catalyst designated M3 had the highest activity, which was near the activity of Ru, Ir, or Ag. As M3 was much cheaper than the noble metal catalysts, it was subsequently used for HTP decomposition reactor experiments and compared to an $\text{Ir}/\text{Al}_2\text{O}_3$ catalyst. The tests used two different catalysts in a smaller (19 mm D $\times$ 38 mm L) reactor with 50–80% HTP and a mass flow of 15–23 g/s and then the M3 only in a larger (196 mm D $\times$ 90 mm L) reactor with 92% HTP and demonstrated good startup and shutdown transients for a gas generator application. The mass flow was 758 g/s, and the chamber pressure was 1.58 MPa. The highest catalyst bed temperature was 1033 K (760 °C), and the gas temperature reached 1063 K (790 °C).

A patent [522] for transition metals (Mn, Ag, Ru, Pb, V, Cr or Co, or other transition metals or noble metals, such as Cu or Pt) oxides deposited on a porous catalyst base of either zeolite molecular sieves, porous alumina, silica or aluminosilicate, or high surface area ceramic materials all in the form of a porous monolith, a honeycomb or chunks, extrudate, pieces, pellets, spheres uses preparation methods of impregnation, drying and calcining similar to those described in an earlier patent by the same inventor [523].

Manganese oxides, palladium, platinum, ruthenium, and silver were deposited on $\gamma\text{-Al}_2\text{O}_3$ and Si-doped Al_2O_3 spheres, starting from different precursors during the impregnation phase [524]. Metal loadings on the ceramic substrates were evaluated by SEM/EDAX, and the activity of different catalysts in the decomposition of 30% H_2O_2 was measured in a laboratory apparatus. The platinum penetration extends down to 180 μm below the surface, about half of the pellet radius. The $\text{Pt}/\text{Al}_2\text{O}_3$ 2nd type (LR-59) catalyst was found to be the most active, showing an excellent repeatability and no appreciable poisoning.

Two different active metal impregnation techniques were used to prepare supported $\text{Pt}/\text{Al}_2\text{O}_3$ and Pt/SiC catalysts for HTP decomposition on spheres and granules of several alumina-based carriers (lanthanum doped alumina, bimodal δ -alumina and θ -alumina, silicon carbide, and α -alumina) with Brunauer Emmet Teller (BET) surface areas between 4 and 200 m^2/g [525]. The alumina supports, five different types, were in spherical form, manufactured by SASOL with diameters ranging from 0.6 to 2.7 mm. A granular silicon carbide support with an average diameter of 0.55 mm and a specific surface area lower than 1 m^2/g was also used, but platinum adhesion was unsatisfactory. Twelve catalysts with different carriers, different active metal loading, and different impregnation methods were prepared and tested. Chemical activity and thermal shock resistance of finished catalysts were measured, and SEM-EDAX measurements of the platinum load on the supporting surface were used to assess the effectiveness of the active metal deposition and monitor the catalyst degradation caused by 87.5% HTP decomposition. Two of the $\text{Pt}/\alpha\text{-Al}_2\text{O}_3$ catalysts, including $\text{Pt}/\alpha\text{-Al}_2\text{O}_3$ catalyst LR-III-39, showed high chemical activity and excellent thermomechanical strength, with

no signs of platinum loss because of hydrogen peroxide decomposition. High surface loads of platinum (44 mass-% on the surface) were achieved on the α - Al_2O_3 substrate despite its relatively low surface area ($4 \text{ m}^2/\text{g}$), successfully overcoming the limitations usually associated with active metal deposition on low surface area substrates. One of the catalyst impregnation methods may represent an effective alternative to the incipient wetness impregnation technique traditionally used for the synthesis of heterogeneous catalysts.

A commercial 0.6 mm diameter spherical γ - Al_2O_3 made by SASOL with a surface area of $170 \text{ m}^2/\text{g}$ was used as the support for a $\text{Pt}/\text{Ce}_{0.6}\text{Zr}_{0.4}\text{O}_2$ wash coat [526]. The as-received carrier was first sintered in air at 1373 K (1100 °C) for 1 h in order to obtain the desired crystal phase with a measured BET surface area of about $74 \text{ m}^2/\text{g}$. The second step consisted in the preparation of a sol/gel containing Ce/Zr in a 60-to-40 atomic ratio, starting from the corresponding nitrates in the presence of citric acid and following a procedure already described in the literature. The third step consisted in coating the Al_2O_3 spheres with the $\text{CeO}_2/\text{ZrO}_2$ sol/gel precursor by wet impregnation and absorption. After impregnation, the samples were calcined at 823 K (550 °C) for 6 h. The fourth step was the deposition of Pt by a modified ion exchange method using either an aqueous $\text{Pt}(\text{NH}_3)_4(\text{NO}_3)_2$ solution or a H_2PtCl_6 solution in acetone. For some of the samples, the $\text{Pt}(\text{NH}_3)_4(\text{NO}_3)_2$ platinum precursor solution was directly added to the Ce/Zr sol prior to coating it onto the alumina substrate, but the end results were discouraging. Finally, the samples were calcined at 773 K (500 °C) for 4 h and reduced in flowing H_2 at 673 K (400 °C) for 4 h. The final Pt loading was 6 to 10% by mass. Based on laboratory tests with 30% H_2O_2 , followed by scanning electron microscopy-energy dispersive X-ray spectroscopy (SEM-EDX) and X-ray diffraction (XRD) examination, a sample with the designation CZ-11 which had been impregnated with a H_2PtCl_6 solution in acetone, resulting in a final Pt loading of 10% by mass, exhibited the best performance in terms of chemical activity and repeatability. The same catalyst was later used in a thruster test (*Encyclopedia of Monopropellants*, the chapter “Hydrogen Peroxide Monopropellants”).

A team from the University of Pisa, Italy, and ALTA S.p.A., Italy, developed a platinum catalyst that was then tested for durability in an actual flight-worthy thruster and analyzed by SEM-EDAX [527]. This is a nicely illustrated paper and shows excellent quality SEM images and EDAX scans of the catalyst before and after firing in the rocket engine.

Four different catalyst beds were evaluated under operational conditions representative of typical application in small monopropellant thrusters to characterize the resulting performance of the thrusters [528]. The catalyst beds were integrated in a reconfigurable flanged 6.5-N thruster prototype and tested at sea-level pressure. The catalysts consisted of platinum deposited on α - Al_2O_3 or $\text{Ce}_{0.6}\text{Zr}_{0.4}\text{O}_2/\text{Al}_2\text{O}_3$ carriers. The preparation of this catalyst had already been described [526]. Two different substrates, respectively, indicated as 0.6/4 and 0.6/75 and produced by SASOL GmbH, have been used as catalyst carriers. The 0.6/4 support consisted of α - Al_2O_3 with a BET

surface area of $4 \text{ m}^2/\text{g}$, while the 0.6/75 substrate was a mixture of α and θ alumina, with a one-order-of-magnitude-higher BET surface area ($75 \text{ m}^2/\text{g}$). Three platinum catalysts, indicated as LR-III-97, LR-III-106, and LR-IV-11, were prepared using proprietary coating techniques. Another platinum catalyst, indicated as CZ-II-600, was prepared as reported by Romeo et al. [529]. The thruster was designed to operate with 5 g/s of 90% H_2O_2 at a nominal chamber pressure of 15 bar and $10 \text{ kg m}^{-2} \text{ s}^{-1}$ of bed loading (25 mm catalyst-bed diameter), developing a nominal thrust of 6.5 N. Three conical nozzles were used to change the bed loading and allow atmospheric operation of the thruster without nozzle flow separation at three values of mass flow rate (5, 17, and 28 g/s) and the same chamber pressure (15 bar). The main element of the thruster is the cylindrical casing, which was interfaced at the upstream end with a flanged connection to the thrust balance and at the aft end to a threaded nozzle. All beds showed high decomposition efficiencies, well in excess of 90%. In particular, two catalyst beds (indicated as LR-III-106 and CZ-II-600) were able to decompose up to 13 and 11 kg of 90% hydrogen peroxide (equivalent to 433 and 366 g of decomposed H_2O_2 per gram of catalyst) in 2500 and 2000 s of continuous thruster operation. They exhibited c^* efficiencies higher than 95%. The experimental results also indicated two main sources of catalyst degradation. In low-porosity catalysts, the decay of chemical activity affects the temperature efficiency and causes the flooding of the first portion of the catalytic bed, whereas highly porous catalysts experience thermal cracking and rupture of the carrier, which leads to excessive growth of the pressure drop across the catalytic bed. With the LR-IV-11 catalyst, there was a progressive increase in the pressure drop across the bed. However, the increase in the pressure drop did not affect the correct operation of the cavitating venturi, and therefore the thrust remained essentially constant. As in the case of LR-IV-11, the occurrence of excessive pressure losses, rather than the degradation of its catalytic activity, caused the termination of the run.

All-Metal Catalysts

Many of the studies on the effects of all-metal catalysts on dilute hydrogen peroxide solutions were done to develop electrodes for fuel cells. In fuel cells, electrodes should actively reduce hydrogen peroxide while current is drawn, but they should not decompose hydrogen peroxide during idle times. Other types of non-catalytic electrodes are needed for polarographic studies of H_2O_2 redox reactions and conductivity or pH measurement in H_2O_2 solutions.

A porous, cobalt-plated steel screen catalyst for the decomposition of hydrogen peroxide can be made by electroplating an iron or steel screen first with copper and then in a bath with sacrificial cobalt anodes to give a coating of 0.007 in. of cobalt [530]. The final coating is rough, porous, and fernlike. Its activity can be increased further by dipping it in hydrogen peroxide and allowing it to dry.

A study of the catalytic decomposition of acidic H_2O_2 solutions (10^{-4} to 10^{-1} M) in the presence of platinum, iridium, palladium, and gold showed that in H_2SO_4

solution, platinum, iridium, and palladium are catalytically active, but gold is not active [531]. The H_2O_2 decomposition is a first-order reaction with the following kinetic constants: $k = 6 \times 4 \times 10^{-5} \text{ s}^{-1}$ for platinum; $k = 1 \times 2 \times 10^{-5} \text{ s}^{-1}$ for iridium; $k = 0 \times 34 \times 10^{-5} \text{ s}^{-1}$ for palladium; all at 298 K (25°C) and referred to a 10 cm^2 metal surface. The surface of the electrode practically becomes covered by a monomolecular layer of oxide during the catalytic H_2O_2 decomposition in acid solution. The metal loses its catalytic activity when it cannot be covered by an adsorbed oxide layer, as when it forms complexes with the solution: for instance, Pt and Ir in HCl solutions or Au in H_2SO_4 solutions.

Silver and platinum metals are known as active catalysts for hydrogen peroxide reduction and decomposition, but their relative activities were not well known, and data were also lacking with respect to the relative rates of reduction and decomposition of H_2O_2 in contact with different catalysts and electrode materials. The rates of H_2O_2 reduction and decomposition at different electrodes that are catalytically active in these reactions and relatively corrosion-resistant in alkaline solutions were measured, including Ag, Au, Pt, and Pd, the alloy Pd-Ru, the surface Raney-nickel catalyst Ni-SRC, as well as Ni-SRC coated with an electrolytic palladium deposit, Pd/Ni-SRC [532].

Heterogeneity of the surface of metals of the copper group can be observed in the decomposition of hydrogen peroxide [533]. The distribution curves of the active centers with respect to their activation energy indicates that there are active centers with different activation energy on the surfaces of both single crystals and polycrystalline samples. The (100) faces, which are more closely packed, are characterized by lower activation energy. Thermal treatment of silver in air or under vacuum produced changes in the values of the most probable activation energy of the process. This phenomenon relates to the amount of oxygen on the surface and in the bulk of silver.

4.10.2.5 Metallic Silver Catalysts

The widely used silver (stacked screen or rolled screen) catalyst beds are typically made of 12 to 40 mesh/in. screen (wire mesh, gauze) and are either activated by etching with dilute nitric acid and/or by coating with calcined samarium oxide. These screens nominally have a pressure drop of 552 kPa (80 to 90 psid) across the bed, are relatively heavy, and are easily poisoned by typical stabilizers often found in HTP. The weave pattern of the silver wire mesh screens is sometimes described as a “herringbone weave”.

In Russia, catalysts based on silver and its alloys were prepared as wire grids, cocoons, and porous briquettes. In practice, pure silver catalysts did not find wide application, except for water and oxygen production in life support systems when cleanliness of decomposition products should be the highest [534]. Based on experience in Russia, pulse-mode operation of catalyst beds due to high thermal conductivity of silver an overheating of the injector head and valve area may occur, which in turn may result in explosive HP decomposition near the injector manifold. The catalyst activ-

ity of silver does not provide a start capability of catalyst beds at temperatures below 273 K (0 °C) with the characteristics required for thrusters.

There is always the concern about the poisoning effect of stabilizers on the activity of silver catalysts. It is important to compare stabilized and unstabilized HTP side-by-side [535]. Unfortunately, many catalyst tests reported in the mid-1990s did not identify the stabilizers in the HTP that was passed through the catalyst.

A method was developed for preparing silver surfaces that were reproducible in their reactivity toward both dilute and concentrated H_2O_2 , as evidenced by the rates of oxygen evolution measured in a static-type constant volume reaction chamber [536]. The pure metal was found to be more reactive to H_2O_2 than metal that had been either tarnished by exposure to the atmosphere or given a $\text{Sm}(\text{NO}_3)_3$ treatment. In the case of tarnishing, the initial reaction rate is believed to be controlled by the diffusion of H_2O_2 through a layer of combined oxygen on the silver surface.

The solubility of silver in 15 to 80% hydrogen peroxide was determined by direct means and by evaluating the $[\text{Ag}^+][\text{HO}^-]$ ionic product needed to start rapid catalysis [537]. Solubility was constant from 262 to 298 K (–11 to +25 °C). The rate of dissolution of silver metal in concentrated hydrogen peroxide solutions decreased progressively with time and approached zero when the solution became essentially saturated. Dissolution rates of silver in hydrogen peroxide at strengths over 50% were diffusion controlled. The addition of a little alkali to H_2O_2 solutions containing silver ion quickly initiates a more rapid decomposition with the simultaneous formation of a solid phase, which can be shown to be metallic silver. In solutions of H_2O_2 containing $\text{Ag}(\text{I})$ ion, rapid catalysis was initiated when the solubility product of silver(I) hydroperoxide (AgO_2H) was reached. The attainment of the solubility product of AgO_2H is postulated as the criterion for rapid catalysis in solutions of hydrogen peroxide containing silver ion. If NaCl was present, AgCl precipitated in the diffusion layer. Both the diffusion of $\text{Ag}(\text{I})$ ion from the silver surface and of chloride ion to the silver surface were considered in a study of concentration gradients.

Electronic conductivity measurements revealed that pH increased proportionally with the amount of silver dissolved, giving higher values at the two extremes of concentration than at intermediate concentrations [538]. The accelerating rate of decomposition that occurs when such solutions become saturated with these ions results from the continuous precipitation of particles of silver as decomposition proceeds. As further decomposition decreased the H_2O_2 concentration, Ag^+ and HO_2^- were removed from solution in accordance with the limiting ionic product.

The rate of decomposition of hydrogen peroxide on a smooth silver surface at 273 K (0 °C) rises linearly with concentration of peroxide up to about 50–60 mass-% and then becomes independent of the concentration up to about 70–80 mass-% H_2O_2 . At still higher concentrations the rate rises again [539]. It was tentatively concluded that decomposition occurs by a strictly heterogeneous mechanism at the metal/liquid interface in concentrations up to about 70–80 mass-%, but that a free-radical chain mechanism is superimposed above this concentration.

Measurements of the rate of the catalytic decomposition of H_2O_2 on the surface of single crystals of silver showed that the kinetics depended strongly upon the concentration and pH of the H_2O_2 solutions [540]. Even under the conditions causing the least change in the surface during reaction the rate constants were the same for all the orientations examined. During the reaction the surface became covered with a layer, possibly silver oxide, which masked the original orientation of the crystal; the formation of this inhibiting layer is the most likely reason for the absence of any orientation dependence. Silver(I) ions were found in the solution.

A hydrogen peroxide decomposition catalyst can be made by silver plating a stainless-steel screen with coarse, porous silver, coating the porous silver with potassium permanganate and baking it in place [541]. This catalyst can start the decomposition of HTP only once at temperatures below 273 K, but it can restart repeatedly if the catalyst and propellant temperature is above 294 K (21 °C).

The decomposition of hydrogen peroxide at silver surfaces showed that two distinct decomposition regions exist with an abrupt transition from one region to the other that occurs at about 291 K (18 °C). The low temperature reaction rates were measured in a static system with active stirring at constant temperature and constant pH. A small piece of silver wire was cleaned, weighed, and dropped into the stirred solution. The gas evolution was measured with a wet test meter. At low temperatures, the rate of HP decomposition was proportional to the product of wetted area times the HP concentration [542]. The rate of silver mass loss was proportional to product of wetted area times the square of the HP concentration. If the rate of silver mass loss (spanning four orders of magnitude) is plotted in a double-logarithmic graph versus the HP concentration, one obtains a nice straight line. The rate of silver loss was inhibited by the presence of silver and hydroxide ions in the HP solution and decreased when increasing the pH from 2 to 3. The data at low temperatures indicated that a chemical reaction at the silver surface controls the rate of HP decomposition. The activation energy determined from the slope of the Arrhenius plot was 43.5 kJ/mol (10.4 kcal/mol). A chain mechanism thought to be consistent with the experimental evidence was postulated. Expanding the range of temperatures tested to higher temperatures, the heterogeneous decomposition of 90% H_2O_2 on silver was investigated as a function of the bulk solution temperature, silver surface temperature, and pressure [543]. The apparatus used for study of the high-temperature decomposition differed from the one used for the study of the low-temperature decomposition. A dynamic rather than a static reactor had to be used. The dynamic reactor consisted of a 6-mm (0.25 in.) long piece of 0.12 mm (0.125 in.) diameter silver rod held at the tip of a hypodermic needle with an internal thermocouple. A supply of HTP flowed at a rate of 45 g/min through a pressurized hot water bath for pretest temperature conditioning, over the catalyst, and the reaction products were cooled, passed through a backpressure regulator, and the amount of gas evolved measured in a wet test meter. At high temperatures, the decomposition of 90% HP is rate-limited by heat transfer. At constant bulk solution temperature, the silver surface temperature, and the HP decomposition rate increased

with increasing pressure in the manner expected for a heat-transfer-limited process. At constant pressure with increasing bulk solution temperature, the silver surface temperature slowly increased, while the HP decomposition rate and the silver loss rate slowly decreased.

It has been claimed that coating the silver with oxides of elements from IUPAC Group 12 (former Group IIb) of Mendeleev's Periodic Table of the Elements in an amount such as to cover at least 10%, but not more than 90% of the silver surface, i.e., coating with zinc oxide or cadmium oxide, will form catalysts that are capable of decomposing much greater amounts of hydrogen peroxide per unit weight of silver lost than with prior art catalysts with an all-silver surface [544]. Zinc or cadmium are applied to roughened silver surface as a solution of their nitrate or formate salts, and dried and baked to form the oxides. It is not necessary to coat all silver screens in the catalyst bed. It suffices to insert the coated (e.g., 0.5–1.5 mg ZnO or CdO /cm² of silver surface) silver screens into the upstream section of the bed, where some of the zinc or cadmium is leached and reduces silver loss rates in the downstream sections of the bed.

The decomposition of liquid H₂O₂ on a silver catalyst is complicated by the existence of a vapor barrier at high peroxide concentrations. The barrier arises because localized decomposition at the catalyst surface raises the temperature of the silver far above the boiling point of the hydrogen peroxide, and any liquid approaching it is vaporized. Passing cooling water through a silver catalyst tubing can lower its temperature and suppress the vapor barrier [545]. Under these conditions the decomposition is changed and approaches the expected behavior. The vapor barrier is also diminished by increasing the pressure, which supports the thesis that the vapor barrier retards the chemical kinetics of the decomposition. As the pressure in the reaction chamber was increased, the silver loss was decreased.

The catalytic decomposition of hydrogen peroxide on silver follows a second-order reaction in 10–25M solutions [546]. In the range of lower concentrations, it follows first-order kinetics. During the decomposition the catalytic activity of silver diminished, depending on the solution concentration and various other experimental conditions. The gradual inhibition was caused by a partly irreversible sorption of the reaction product oxygen. Oxide layers were formed only in 2–5M H₂O₂ solutions. Decomposition and gradual inhibition were rarely influenced by the effects of metal dissolution by the reactants, by the surface changes, or by silver ions in solution.

The kinetics of silver-catalyzed decomposition of concentrated hydrogen peroxide solutions on a catalyst that was made in the form of a rotating disk was investigated as a function of bulk solution and silver surface temperatures and of different speeds of disk rotation [547]. An abrupt transition between regions of lower to higher decomposition rate occurred with an increase of temperature, similar to the transition from nucleate boiling to film boiling. Hydrogen peroxide decomposition in the region of a lower reaction rate was surface-reaction controlled. From experimental data in this

region, the rate was proportional to the square root of hydrogen peroxide activity. The activation energy was 55.6 kJ/mol (13.3 kcal/mol).

The decomposition of H_2O_2 on silver and gold follows basically different reaction mechanisms, which are not only different limiting cases of one mechanism. The decomposition of H_2O_2 on silver-gold alloys in the concentration range from 5 to 0.05 M H_2O_2 and in the temperature range from 283 to 333 K (10 to 60 °C) at pH 8 on oxide-free contacts transitioned continuously from second order with silver (above 0.3 M H_2O_2) to first order with gold [548]. The experimental activation energies and pre-exponential factors increased from silver to gold at first less strongly and later more so. The catalyst behavior was primarily determined by the oxygen affinity of the catalyst, in respect to which gold and silver differed substantially, although otherwise they have largely similar properties.

Both silver-plated nickel 200 screens and pure silver screens were used as the active metal catalyst for decomposition of 85% HTP during the development of a pressure-fed liquid fueled upper-stage bipropellant engine with an HTP predecomposition chamber [549]. The catalyst bed variables tested were screen material, screen loading configuration, screen plating and coating processes, screen mesh size, bed loading, and catalyst bed head loading uniformity. A modular, cartridge type, nominal 50-lb_f monopropellant rocket engine was used for performance evaluation of catalyst bed designs. The diameters of the catalyst bed and the engine throat were 2.4 cm (1 in.) and 0.79 cm (0.311 in.), respectively. The c^* efficiency of the predecomposition reactor performance was used for the evaluation of catalyst activity and decomposition efficiency. The data indicated that a high decomposition efficiency (>90%) of 85% HTP could be achieved at a bed loading of 7.1 kg cm⁻² s⁻¹ (0.51 lb_m in⁻² s⁻¹) with pure silver screens. This performance was duplicated with silver plated, nickel 200 screens. Samarium oxide coating on silver plated nickel 200 screens was also evaluated but retarded the decomposition process, and the catalyst was flooded at lower bed loading. The effects of catalyst bed aging were investigated to determine the degree of deterioration in the performance of the catalyst bed with cumulative runtime. A throughput of 90.6 kg (200 lb_m) of HTP was achieved during 1000 s runtime with performance degradation beginning only after approximately 400 s. The starting transients experienced were disappointingly long at ambient temperatures. Fourteen catalyst bed configurations were tested in an effort to provide design data. In addition to the nominal 50-lb_f monopropellant engine, a subscale engine with a 3.5-in. diameter catalyst bed was used to verify the scalability. Over 250 tests were performed before the final selection of the catalyst bed configuration. The decomposed gas had a sufficiently high temperature to ensure the auto-ignition of JP-8 fuel in the bipropellant engine to be tested next.

In addition to the silver screen catalysts described above, solid catalysts using precious metals (Pt, Ir on alumina) were also developed for the decomposition of HTP with 85 to 98 mass-% H_2O_2 [550]. Preliminary results showed that the catalyst had a strong reactivity even after 15 min of H_2O_2 decomposition. The development effort

also included some homogeneous catalyst testing. Various non-toxic catalysts were evaluated with 98% peroxide and hydrocarbon fuels. The results of open cup drop tests indicated ignition delays around 11 ms.

Silver Plated on a Nickel Screen

A catalyst bed made from silver-gold alloy plated on nickel screen and stacked screens inserted in a catalyst bed showed short startup times and long endurance operating times [551]. The nickel screen is electro-etched and rough nickel plated to roughen its surface (to give it a “rugose” surface) prior to plating with the silver-gold alloy. The silver-gold alloy contains about 99% Ag and 1% Au.

In order to make a catalyst, a 20 ×20 mesh nickel screen was first flame-sprayed with a coating from an alloy of 70% Ag/30% Pd, then roughened by etching with nitric acid and activated by immersion in a 10% aqueous solution of $\text{Sm}(\text{NO}_3)_3$, then baked to obtain a discontinuous coating of samarium oxide [552]. This catalyst was very active with 98% H_2O_2 , and 90% of steady-state chamber pressure was attained within 190 ms. Similar results were obtained when the nickel screen was flame-sprayed with an alloy of 70% Ag/25% Pd/5% Mn.

Silver plated on nickel screen was used in subscale 1-in. and 3.5-in. diameter reactors during the development of a catalyst bed for a large Upper Stage Flight Experiment H_2O_2 /JP-8 bipropellant engine [553]. The evaluation was performed with two different bed diameters. A 50-lb_f monopropellant engine with a 1.0-in. ID reactor was used to determine the optimal catalyst bed configuration, and a subscale engine with a 3.5 in. diameter reactor was used to verify the scalability. Silver-plated nickel 200 screens were used for the catalyst bed. Over 250 tests were performed before the final selection of the catalyst bed configuration. The catalyst bed design variables included bed loading, screen material, screen loading configuration, screen plating processes, screen mesh and wire size, catalyst bed head load uniformity, operational characteristics, and the cost of catalyst bed. It was previously reported that pure silver metal was found to be more reactive with hydrogen peroxide than silver metal which had been either tarnished or treated with $\text{Sm}(\text{NO}_3)_3$. In the tests at Kaiser Marquardt, the $\text{Sm}(\text{NO}_3)_3$ -treated silver-plated screens afforded a “catalyst” that was not reproducible in activity towards H_2O_2 . The results of the tests with 85% H_2O_2 agreed with previously reported findings. In order to maintain high decomposition efficiency, the silver screens were not coated with samarium oxide in the Upper Stage Flight Experiment H_2O_2 /JP-8 engine catalyst bed development program.

It was noted that pretreatment with hydrogen peroxide promotes the initial catalytic activity of the silver screen catalyst plated on nickel screen [554]. The results indicated that the initial activity and the startup performance of the catalyst were greatly improved by the pretreatment with 90% HTP. Scanning electron microscopy and X-ray photoelectron spectroscopy results showed that fissures and active species of Ag_2O appeared on the silver screen surface after the pretreatment. These are probably the main reasons for the improvement of the catalyst activity.

Silver Plated on a Copper Screen

A catalyst bed made from copper screen that was coated with silver by flame spraying and then anodized in an alkaline carbonate bath and then ammoniated in an ammonia bath in which silver oxide has been dissolved is described in [555–558]. Catalyst supports in which the catalyst is metallic silver are anodized in a bath of sodium carbonate solution until a full block anodized film is obtained on the silver, and then ammoniated by immersion in 25% ammonia solution for at least 2 h. The catalyst supports may be pellets consisting predominantly of sintered silver (e.g., 93% silver, 7% copper); or pure nickel or stainless steel provided with a nickel surface flash, overlaid with copper and finally coated with silver. The anodizing can be carried out in the range 20 A/sq. ft. for 3 min to 11 A/sq. ft. for 3 h. Instead of plating silver on a copper screen, one can also mix silver powder with copper powder and press and sinter them into pellets [559]. The pellets are then anodized and ammoniated, similarly to the method proposed for the treatment of screens.

Silver Plated on a Stainless Steel Screen

Silver cannot be electroplated on stainless steel without a primer flash of gold and/or copper.

Instead of electroplating or flame spraying silver onto stainless steel wire mesh, it was attempted to sinter a dip coat of silver powder, ceramic oxides, and various binders onto stainless steel wire mesh [560, 561]. This catalyst was intended for sustained decomposition of 90% HTP or even 98% HTP. A basic catalyst formulation consisted of a mixture of silver powder, manganese(IV) dioxide, and aluminum oxide. A suspension of the powders in oil and slow drying lacquers, the catalyst mixture was applied as a coating on stainless steel screen, dried, and calcined. It was found that adding gold to the basic catalyst improved the activity up to a maximum for a gold concentration of about 2.5%. Adding glass powder to the formulation improved the adherence of the coating. Catalyst activity declined with increasing sintering temperatures. However, even for a sintering temperature of 1339 K (1950 °F), the catalyst gave a decomposition rate 33% higher than that of conventional silver-plated stainless screen catalysts. Substituting samarium oxide for part of the aluminum oxide in the basic formulation eliminated the need for final activation. Using 40 to 60% of samarium oxide in place of aluminum oxide improved activity and the adherence of the coating.

Silver Plated on a Brass Screen

The steam generator used to drive a turbine that drove the propellants pumps on the X-15 supersonic research plane used silver-plated brass screens. There were problems with the silver plating delaminating from the brass base and propellant channeling through the bed [562, 563].

Silver Alloy Catalysts

This section deals only with all-metallic silver alloys as catalysts. Alloyed supported catalysts are discussed in a different section. Silver-gold and silver-platinum alloys were found to have a higher activity than silver metal, samarium nitrate-treated silver, or silver-silica cermets. The enhancement of silver catalytic activity by gold is offset by the ability of gold to alloy with silver. The use of smaller proportions of gold makes it possible to prepare a catalyst having a continuous phase of silver flocked with Ag-Au alloy. A mixture containing 10.7% Au was pressed into a pellet and examined under a microscope. Distinct areas of two different materials were observed. Heating to 1273 K (1000 °C) did not alter the structure. Catalytic activity toward 87% H_2O_2 was high and remained high. A higher concentration of gold tended to form continuous phase alloys with lower activity. A silver/platinum catalyst gave extremely high activity, which, however, dropped markedly after heating the catalyst to 1273 K (1000 °C).

A layered catalyst bed patented in [564] consists of an upstream section with pelletized sintered 95% silver/5% Cu 3-mm diameter pellets and a downstream section with stacked 20-mesh copper screens plated with silver.

Metallic Gold Catalysts

Radiolysis of heavy water in a pressurized water nuclear reactor will produce D_2O_2 , an unwanted contaminant. A study of the heterogeneous catalytic decomposition of both hydrogen peroxides in heavy water showed that the catalytic decomposition of H_2O_2 in H_2O or D_2O_2 dissolved in heavy water (both on the surface of glass in alkaline medium and on metallic gold) is different. The results, compared with those obtained under similar conditions for H_2O_2 in ordinary water, indicated that D_2O_2 was much more stable than ordinary H_2O_2 toward gold catalysts [565].

A study of the catalytic decomposition of acidic H_2O_2 solutions (10^{-4} to 10^{-1} M) in the presence of gold showed that in H_2SO_4 solution gold is not active [531]. Silver-gold alloys are among the most active catalysts for HTP decomposition that have been reported [566].

4.10.2.6 Platinum Group Metal Wire Mesh Screens and Foils

Defect sites in crystal lattices are better catalysts than perfectly ordered crystals. The decomposition of dilute solutions of hydrogen peroxide on platinum foils is dependent on the crystalline state of annealed or worked (wrinkled) platinum foils [567]. The first-order reaction rate constant was found to increase with the degree of cold work, and a direct relationship between the catalytic activity of the platinum and its degree of deformation was established. The increase in activity is apparently directly due to deformation since the possible effects of preferred orientation and increased surface area proved to be negligible.

The catalytic decomposition of dilute aqueous solutions of hydrogen peroxide has been studied on several IUPAC Group 8, 9, 10 metals and binary alloys, includ-

ing palladium-gold [568]. This was not done for rocket but for fuel cell applications. The kinetics were measured at 300 K (27°C) as a function of the catalyst composition and pH of the solution. In neutral solutions, the activity of the individual metals of the third period of Group 8, 9, 10 was generally greater than those of the second period, the order of specific activity (per unit surface area) decreasing in the sequence $\text{Pt} > \text{Os} > \text{Ir} > \text{Pd} > \text{Ru} > \text{Rh}$. Alloys of $\text{Pt}\bullet\text{Pd}$, $\text{Pt}\bullet\text{Ru}$, and $\text{Pt}\bullet\text{Rh}$ showed activities intermediate between those of the constituent metals. Alloys of $\text{Pt}\bullet\text{Ir}$ and $\text{Pd}\bullet\text{Au}$ exhibited maximum activities at intermediate alloy compositions. The kinetics depended strongly on the pH of the solutions, the rate rising to a sharp maximum at pH values of 10–11, in accordance with a postulated radical-chain mechanism for the decomposition.

A stacked screen wire mesh catalyst made from annealed nickel wire flame-sprayed with an alloy containing 20–35% Pd and 65–80% Ag and coated with a film of Sm_2O_3 (formed by five consecutive immersions in a 10% $\text{Sm}(\text{NO}_3)_3$ solution and calcination at 811 K (1000°F) for 5-min cycles) was tested in a rocket engine with 98% HTP [569]. The engine had a very short response time, and 90% of p_c was reached within 90 to 40 ms.

4.10.2.7 Nickel and Nickel Alloy Wire Mesh Screens and Porous Pellets

Because all-silver catalyst packs have poor startup capabilities, and the high thermal conductivity of silver allows more heat to soak back to the injector and valve area of thrusters during operation and in particular during heat soakback after shutoff in pulse-mode operation, Russia has placed emphasis on development of catalysts based on nickel and nickel alloys [534]. In order to eliminate the aforementioned drawbacks, a new technology of silver deposition on stainless steel grids with subsequent activation was developed. The catalyst designated as K-86 had good mechanical strength and high specific activity; however, due to its grid form the specific surface of the given catalyst inside bed was low. In contrast, the specific surface and the activity of catalysts based on porous metal materials impregnated with potassium permanganate (designated K-87) were much higher. Catalyst K-87 had high activity and a long operating life. It was made from porous nickel tablets impregnated with the potassium permanganate. The catalyst was available as 4–5-mm tablets, and the porosity of catalyst bed ranged from 40 to 50%. Catalyst K-87 enabled the start of catalyst beds at temperatures down to 233 K (–40°C).

4.10.2.8 Supported Metal Catalysts

In analogy to supported metal catalysts used for the decomposition of hydrazine as a monopropellant, supported metal catalysts are equally effective for the decomposition of hydrogen peroxide, but very sensitive to poisoning by stabilizers commonly added to HTP.

Supported Platinum Group Metal (PGM) Catalysts

Ruthenium in the form of ammonium ruthenium(III) chloride, as a coating on alumina pellets or on nickel wire mesh, as ruthenium(III) chloride solution, or as a metallic sponge was patented as a catalyst for H_2O_2 decomposition [570]. The same palladium catalyst that allows the direct synthesis of H_2O_2 from its elements will also cause decomposition of H_2O_2 [122].

The activity of various catalysts for the decomposition of hydrogen peroxide was studied with platinum supported on silica or silver, iridium, platinum/tin or manganese oxides supported on alumina [571]. The activity was measured using two different reactors: **(1)** a conventional constant pressure reactor for the determination of the gas evolution versus time using diluted H_2O_2 solutions and **(2)** a constant volume reactor to measure the pressure increase using more concentrated solutions. The first reactor allows the determination of the kinetic order of the reaction, a comparison of the activities of the different samples, and the characterization of the potentially poisoning influence of some stabilizers of H_2O_2 solutions on the catalytic activity. Two kinetic orders were found, depending on the catalyst: a zero order and a first order. The shape of the catalysts' samples is an important parameter, with powders always being more reactive than grains and pellets. The catalyst activities are listed here in the order of increasing activity: $(\text{Pt} + \text{Sn})/\text{Al}_2\text{O}_3 < \text{Ir}/\text{Al}_2\text{O}_3 < \text{Pt}/\text{SiO}_2 < \text{MnO}_x/\text{Al}_2\text{O}_3 < \text{Ag}/\text{Al}_2\text{O}_3$. The presence of a pyrophosphate stabilizer led to a loss of activity, mainly as a result of passivation in the case of MnO_x -supported samples, whereas the presence of stannate slightly increased the activity of silver/alumina and exerted no influence on the manganese oxide catalyst samples.

Two supported platinum on spherical γ -alumina catalysts were tested in a heavy-duty flanged reactor with 70 and 87.5% HTP [572, 573]. The reactor was intended as the prototype for a 5-N thruster with 8 mm ID and an L/D of 4.0. The SASOL 06/170 γ -alumina spheres had a diameter of 0.6 mm, a surface area of $170 \text{ m}^2/\text{g}$, and a pore volume of 0.53 mL/g . The two catalysts, LR-57 and LR-59, differed in the way the active metal was deposited. Based on SEM-EDAX measurements, the active metal loading on the surface was about 0.4 atom-% Pt. In the test with 70% HTP, the bed loading was $76.6 \text{ kg m}^{-2} \text{ s}^{-1}$, and the chamber pressure was 0.6 MPa. After only 80 s of runtime, the pressure drop with the LR-59 catalyst increased dramatically due to catalyst breakup. With the 87.5% HTP, the LR-59 pressure drop increased after only 15 s and the test had to be terminated. The performance of the LR-57 catalyst bed was a little better than that of the LR-59 catalyst but it only accumulated 20 s before the pressure drop became prohibitive due to catalyst breakup. These brief run times are several orders of magnitude shorter than what is required in the real world of space propulsion.

The activity of platinum deposited on silicon carbide refractory foam, vitreous carbon open-celled foam, or cordierite ceramic honeycombs with 400 cells per square inch was tested with 30% H_2O_2 solutions [529].

In the wake of premature breakup of γ -alumina catalyst spheres in the LR-57 and LR-59 catalysts, a structural model of the thermal transient and the associated ther-

mal stresses in rapidly heated catalyst pellets was supposed to help in the selection of alternate catalyst carriers resulting in a new Pt/Al₂O₃ catalyst (LR-III-127) [574]. In addition to α -alumina (corundum), cordierite, zirconia, and silicon carbide (carborundum) has been evaluated as catalyst carrier. The pellet breakup problem was solved by using smaller (100 μ m α -alumina granules instead of 600 μ m γ -alumina spheres) and higher stress resistance supports. The LR-III-127 catalyst lasted longer, but only at the expense of increased pressure drop through the catalyst bed as a result of the reduced size of the granules. Progressive occlusion of the catalyst bed due to fragmentation was effectively eliminated.

In South Korea a platinum deposited on alumina catalyst was developed and tested it in 1-N and 50-N thrusters for a microsatellite and upper stage RCS [575, 576]. The catalyst was prepared from γ -type bimodal alumina 1/16-in. pellets from Alfa Aesar that had a surface area of 255 m²/g, total pore volume of 1.14 cm³/g, and median pore sizes of 70 μ m and 5000 Å (bimodal type). The catalyst was impregnated with H₂PtCl₆ solution as a precursor, using the incipient wetness method. Each impregnation was followed by drying (363 K = 90 °C for 12 h), calcination (573 K = 300 °C for 4 h), and H₂/N₂ reduction (573 K = 300 °C for 4 h). The catalyst coating process was done twice to increase the total mass fraction of loaded platinum. After completion of the coating, 23 mass-% of active metal was deposited on the support. The maximum catalyst capacity, which was defined as allowable propellant mass flow rate divided by the volume of the catalyst bed, was 1.27 g s⁻¹ cm⁻³.

Similar 3% Pt/Al₂O₃ catalysts were tested in a small flanged reactor [577]. The best performance was shown for a 30–40 mesh catalyst when the H₂PtCl₆ precursor was dissolved in DI water instead of acetone. The best pH for impregnation was 2.6.

Platinum catalysts initially intended for decomposition of hydroxylammonium nitrate (HAN)-based monopropellants would be equally useful for decomposition of hydrogen peroxide: Spherical granule supports from silica-doped alumina with an average diameter of 1.5 mm were prepared using two procedures starting from the same sol-gel Si-doped boehmite by dripping it into an oil bath, calcining the solidified droplets at 1473 K (1200 °C) and impregnating them with platinum by an incipient wetness procedure, drying at 393 K (120 °C), and H₂-reduction at 673 K (400 °C) [578].

Platinum-based catalysts supported on γ -alumina (grains and pellets) were evaluated using two laboratory scale reactors [579]. The catalysts were characterized by XRD, SEM, and elemental analysis before and after exposure to hydrogen peroxide. Two main parameters were studied: internal (pellets and grains) and external (grains size) surface diffusion. The characterization results of all prepared catalysts showed a homogeneous distribution of platinum particles (average size 1.6 nm) on the support surface. The kinetic study of the catalytic decomposition reaction of dilute H₂O₂ (2 mass-%) showed that decomposition on all platinum-based catalysts followed a first-order kinetic decomposition reaction. Moreover, the granular shape catalysts showed much higher activity than the pellet catalysts leading to a rapid decomposition of H₂O₂. It was shown that the grain size of the catalysts has a strong

influence on the reaction rate of decomposition reaction. For an equivalent amount of catalyst, the external surface increases when the grain size of the catalysts decreases, which leads to a higher catalytic activity.

Comparing a 0.5% platinum on alumina pellets and silver gauze catalyst in a thruster operating with 87.5 mass-% HTP led to the conclusion that the 0.5% platinum pellets had a higher performance, achieving a steady-state decomposition efficiency of 95.4%, with neither catalyst showing signs of exhaustion after several minutes of operation [580]. A commercially available catalyst consisting of 5% platinum on alumina pellets was used for the development of a 20-N thruster [581]; see also [582]. All later tests used commercially procured 5% platinum on alumina pellets.

Nafion is a conductive polymer and has a low melting point. It is not suitable as a catalyst carrier for rockets but has been used for laboratory studies. Pt-Pd aggregated nanoparticles were immobilized on a Nafion-117 membrane to decompose hydrogen peroxide in 0.1-M solutions [583, 584]. The Pt or Pd particles by themselves decomposed hydrogen peroxide only at an insignificant rate, but a bimetallic Pt-Pd catalyst caused steady decomposition at an appreciable rate at room temperature. It remains to be seen if this works also with more concentrated hydrogen peroxide solutions.

Supported Silver Catalysts

After all the success with silver screens for decomposition of hydrogen peroxide in rocket engines, one wonders why not more work has been done with supported silver catalysts. Why should one carry around all the silver buried deep in the core of the silver wires that never gets to see any hydrogen peroxide? Of course, with the conventional silver screens, there is substantial silver loss, and a thin silver coating on the surface of a ceramic catalyst carrier would be lost in a hurry.

Supported silver catalysts were studied many decades ago but did not find any practical applications [585].

Two types of supported catalysts were prepared and compared to silver gauzes reacting with Propulse 89 mass-% H_2O_2 stabilized with 0.1 mg/L phosphate and 4.4 mg/L tin [586]. Discs of silver gauze with a wire diameter of 0.2 mm were stamped out from a sheet, and a known number of discs were compressed into a reactor chamber (12.5 mm D $\times$ 20 mm L), 60 to 100 gauzes weighing about 9 g with a specific surface area of about 40 cm²/g. Alumina-supported silver catalysts were prepared by impregnating alumina carrier with silver nitrate AgNO_3 solution by the incipient wetness method. The support was previously treated in air at 873 K (600 °C) for 5 h and reduced at 573 K (300 °C) for 1 h. Two supports were used: (1) alumina provided by Snecma, spheres 1.2–1.6 mm, BET surface area 250 m²/g; (2) Alcoa alumina, spheres 1.4–2.8 mm, BET surface area 170 m²/g. The active metal loading level in silver was in the range from 5 to 60 mass-%. The supported silver catalyst was compared to a silver screen and a manganese oxide supported on Snecma alumina catalyst containing 10 mass-% Mn. Testing in a rocket engine at sea level was done with

flow rates of 5 g/s. The silver screen catalyst had to be preheated to 373 to 473 K to achieve a startup. If the silver screen catalyst was not preheated, the 89% HTP would shoot right through undecomposed, and the temperature went up by only 100 °C. The 5 or 10% Ag supported catalyst could be started at 293 K and sustained HTP decomposition repeatedly. Increasing the Ag loading beyond 10% Ag did not improve the activity but resulted in less active catalysts. The 5% Ag catalyst was similar to the 10% Ag catalyst. Post-test catalysts removed from the reactor were examined by XRD and TEM. Additional comparative tests were done in a constant volume batch reactor with 30% H_2O_2 . Nanosilver can be deposited on a silica carrier to obtain active HTP decomposition catalysts [587].

4.10.2.9 Metal Oxide Catalysts for Hydrogen Peroxide Decomposition

Metal oxide catalysts can be either simple (binary) oxides of the M_xO_y type or ternary of the type $\text{A}_x\text{B}_y\text{O}_z$, or even multiple mixed oxides of the type $\text{A}_w\text{B}_x\text{C}_y\text{O}_z$. They can be used by themselves (if the powder form they usually start with can be shaped to form erosion-resistant granules for a packed-bed reactor) or deposited onto a catalyst carrier that has the required physical shape and mechanical strength. These metal oxide materials are typically obtained in the form of powders and ceramic processing methods must be used to obtain usable catalyst shapes. The powders can be shaped by fusion, pressing, extruding, sintering, mixing with a ceramic binder and extruding, or by deposition from a slurry onto granular, spherular, or monolithic catalyst carriers.

Many of the metal oxide catalysts described in this section were intended not so much as catalysts for a rocket engine than as catalysts in catalytic oxidation of organic compounds and waste products. Some of the experience gained with those applications will benefit the use of metal oxide catalysts in H_2O_2 monopropellant rocket engines. Unfortunately, several of the publications referenced here describe only work with relatively dilute solutions of hydrogen peroxide, and one will have to extrapolate to higher concentrations that are of interest to a rocket propellant chemist. Reactions in more dilute solutions are of interest for wastewater treatment of test facility rinse waters containing small amounts of H_2O_2 .

Binary Metal Oxides as Hydrogen Peroxide Decomposition Catalysts

Ceramic materials for HTP decomposition have advantages over traditional silver/stainless steel catalysts for their lower weight and better thermal and chemical resistance. Among them, manganese oxides deposited on different supports, such as titania, zirconia, alumina, silica, or cordierite monolith honeycombs, have been a popular choice.

Many transition metal oxides have catalytic activity in the decomposition of H_2O_2 . If they are deposited and supported on catalyst carriers, they can be applied in the form of aqueous solutions of their nitrates as precursors, which are then calcined to convert the soluble nitrates into their insoluble oxides [588]. Because of their high catalytic activity in the decomposition of hydrogen peroxide, oxides of variable multiva-

lence elements are used as promoters in oxygen electrodes of fuel cells and in the treatment of wastewater by oxidation with oxygen and peroxide and could, thus, also be useful as catalysts in monopropellant rockets and gas generators. It has been shown that when hydrogen peroxide acts on solid oxides forming redox systems, a change in the ratio of valence states of the element occurs, leading to changes of chemical composition on the surface and activity of the catalysts.

The vapor-phase decomposition of hydrogen peroxide was studied in a flow system on a wide range of metallic oxide surfaces in the range 311–457 K (38–184 °C) using nitrogen as the carrier gas and H_2O_2 partial pressures up to 1 mm [589]. Oxide surfaces were held on vacuum-flashed metal films, metal strips, or as compressed tablets of the bulk oxide. The activity series, in order of decreasing activity was $\text{Mn}_2\text{O}_3 > \text{PbO} > \text{Ag}_2\text{O} > \text{CoO/Co}_2\text{O}_3 > \text{Cu}_2\text{O} > \text{green NiO} > \text{CuO} > \text{Fe}_2\text{O}_3 > \text{CdO} > \text{ZnO} = \text{MgO} > \text{SnO}_2 > \text{glass (Pyrex}^\circledast\text{)}$. The activity of these oxides may be related to the defect site's density and type and promoting electron mobility.

A study of the decomposition of H_2O_2 on some metal oxide catalysts showed that any oxide of the element that may form a redox system involving two different oxidation states of the element and having a higher standard potential (reduction) E_0 than the corresponding value E'_0 of the system $\text{O}_2 + 2\text{H}^+ + 2\text{e}^- = \text{H}_2\text{O}_2$ is a good catalyst, and oxides having potential E_0 lower than E'_0 are poor catalysts [590].

The kinetics of 0.2-M H_2O_2 decomposition were investigated using ZrO_2 impregnated with transition metal ions (not oxides) by simple immersion in 10^{-3} M solutions of transition metal sulfates, including Ag(I), Cu(II), Hg(II), Co(II), Mn(II), Fe(III), Ni(II) [591]. The amount (mg) of metal ion per g of air-dried ZrO_2 catalyst for Ag(I), Cu(II), Hg(II), Co(II), Mn(II), Fe(III), Ni(II) was 0.53, 3.56, 0.32, 0.91, 2.51, 0.76, and 1.96, respectively. At pH = 6.8, the reaction rate exhibited a first-order dependence on the initial H_2O_2 concentration at low concentrations. The order of activity of the different catalysts was strongly dependent on the H_2O_2 concentration used. The rate increased with increasing pH and attained a limiting rate at higher pH. At lower H_2O_2 concentrations, before the formation of an inhibitory intermediate, the decreasing order of activity was: Ag(I) > Cu(II) > Hg(II) > Co(II) > Mn(II) > Ni(III) > Fe(III). This order can be correlated with both the amount of the metal ion loaded and its redox potential. Comparing Ag(I) with both Mn(II) and N(II) reveals that the redox potential has a pronounced effect. It would be difficult to extrapolate from this work with low H_2O_2 concentrations to actual catalysts useful for rocket applications.

Some metal oxides may not be catalysts in their own right but may be suitable as catalyst supports. The decomposition of hydrogen peroxide that had formed by radiolysis of water in nuclear reactors or spent fuel rod storage depositories and came in contact with corrosion products was studied to better understand corrosion phenomena due to the inadvertent but unavoidable formation and accumulation of hydrogen peroxide under those conditions. Suspended alumina or zirconia particles, corrosion products from deteriorating nuclear reactor fuel elements, will alter the rates of formation and decomposition of H_2O_2 in water-filled pools where spent fuel rods are in

temporary storage, awaiting reprocessing. The studies included Al_2O_3 nanoparticles [140] or ZrO_2 slurries [141]. The activation energy for the H_2O_2 decomposition reaction on ZrO_2 suspensions was $E_a = 33 \pm 1.0 \text{ kJ/mol}$.

In addition to alumina slurries, the adsorption and decomposition of H_2O_2 on nano- and micrometer-sized particles of other ceramic metal oxides, ZrO_2 , TiO_2 , and Y_2O_3 were characterized by measuring the reaction rate constants, the Arrhenius activation energies, and the activation enthalpies for the processes of adsorption and decomposition of H_2O_2 [142]. The experimentally obtained enthalpies of activation for the decomposition of H_2O_2 catalyzed by these materials were $30 \pm 1 \text{ kJ/mol}$ for ZrO_2 , $34 \pm 1 \text{ kJ/mol}$ for TiO_2 , and $44 \pm 5 \text{ kJ/mol}$ for Y_2O_3 . Other ceramic oxides studied included SiO_2 , Al_2O_3 , TiO_2 , CeO_2 , and ZrO_2 [143]. The activation energy was $42 \pm 5 \text{ kJ/mol}$ for the overall decomposition of H_2O_2 independent of the type of oxide. The oxide type had a strong effect on the preexponential rate term with increasing rate in the order of $\text{SiO}_2 < \text{Al}_2\text{O}_3 < \text{TiO}_2 < \text{CeO}_2 < \text{ZrO}_2$. The rate coefficient for H_2O_2 decomposition increased with increasing surface area of the oxide.

In the following, metals from which oxides were formed are arranged in the sequence of groups of the periodic table of elements (New IUPAC version).

Oxides of Group 3 Elements (Sc, Y, La, Rare Earth)

It is strange that for half a century people have been coating silver screens with samarium oxide, but very little work has been done on the catalytic qualities of Sm_2O_3 by itself without the underlying layer of silver. There is very little information on the mixed oxides formed in the $\text{Ag}_2\text{O}/\text{Sm}_2\text{O}_3$ or $\text{AgO}/\text{Sm}_2\text{O}_3$ system and their catalytic properties for H_2O_2 decomposition.

Oxides of Group 7 Elements (Mn, Re)

Next to silver, manganese oxides of various states of oxidation are the most extensively investigated hydrogen peroxide decomposition catalysts. Experimenters have attempted to shape manganese oxide powders into useful shapes (pellets, bricks, monoliths) or deposit them onto ceramic catalyst carriers of a suitable shape. Manganese-oxide based catalysts prepared by an impregnation procedure that involves the wet impregnation of the ceramic support with an aqueous solution of a suitable manganese precursor have certain disadvantages: The anchorage of the active phase onto the support occurs mainly by physical interactions between precursor and the support surface, or the manganese oxide particles are held within the support pores. This technique does not allow a good control of the chemical composition of the final materials as well as of their chemical homogeneity, especially for formulations with multi-component mixed oxides. Catalysts made this way suffer particle fragmentation, active material solubilization, and spalling off, due to the strong erosive power of the H_2O_2 solution impinging on the catalyst at the high temperature generated from its adiabatic decomposition.

Dissolved manganese(II) ions have no catalytic effect. It is quite likely that the catalytic effect of potassium permanganate is due to the reduction of permanganate ion to a finely divided, colloidal form of MnO_2 or its hydrate, which is the actual catalyst [592]. The composition of manganese(IV) dioxide is rarely truly stoichiometric. It is possible that other valences of Mn play a role in H_2O_2 decomposition. The activity of manganese oxide deposited on alumina was at a maximum when the state of oxidation was between 3 and 4. The catalysis by manganese(IV) dioxide may proceed via a redox cycle where manganese oscillates between the trivalent and tetravalent state. In addition to MnO_2 in its pure form, also naturally occurring pyrolusite mineral has been proposed as a catalyst [593, 594].

There are so many papers on evaluation of manganese oxide catalysts for decomposition of hydrogen peroxide that we could select only a few representative ones and we had to arrange them in chronological order.

The activity of supported manganese oxide catalysts as a function of the concentration of manganese on the support showed an increase with decreasing manganese concentration, followed by a sudden decrease for very low manganese concentrations [595]. It depended on oxidation state, pH, support phase modification, and temperature. The catalysts were made by impregnating γ -alumina with $\text{Mn}(\text{NO}_3)_2$ solution, drying, and calcining at 473 K.

A paste made from a mixture of potassium permanganate, potassium dichromate, lead oxide, a ceramic cement, and water was poured into a mold, cut into 8-mm cubes, and calcined at 1173 K (900 °C) to obtain a hydrogen peroxide decomposition catalyst [596, 597].

Manganese oxides precipitated and supported on $\text{Mg}(\text{OH})_2$ had better catalytic activity in the decomposition of 0.1-M H_2O_2 than coprecipitated mixtures of the hydroxides or catalysts supported on MgO. The use of MgO as a carrier for manganese oxides produced a catalyst with higher activity than that of either oxide by itself [598].

Removal of unwanted residual hydrogen peroxide in aqueous solutions is required in many food processing applications where the processing equipment has been sterilized with hydrogen peroxide to remove bacterial contamination. Sometimes, an enzyme, immobilized catalase, is used for this purpose to decompose hydrogen peroxide in the effluent stream. Manganese(IV) dioxide supported on alumina was a more durable catalyst for this application [599]. Kinetic and deactivation studies were conducted in a tubular flow reactor and indicated a first-order reaction.

Electrode potential measurements showed that the state of oxidation of Mn on the surface of manganese oxides (β - MnO_2 , β - Mn_2O_3 , β - Mn_3O_4 , and MnO) varied markedly in hydrogen peroxide solutions [600]. A rearrangement of the surface layer crystal structure takes place as the potential adjusts shortly after the first immersion. On prolonged treatment with hydrogen peroxide, an identical steady state of the surface is established for all the oxides, which is characterized by the very same electrode potential value. The decomposition of hydrogen peroxide includes stages of catalyst oxidation-reduction and electron transfer.

The kinetic parameters of the decomposition of hydrogen peroxide on manganese oxide(s) were determined in the concentration range 0.03 to 1 N and the temperature range 275 to 315 K (1.5 to 42°C) and pH from pH 2 to 10 [601]. The electrode potentials of the oxides and their catalytic activity change in parallel.

The oxidation state of oxide surfaces brought to the state of stationary catalytic activity by H_2O_2 pretreatment corresponds to the oxidation state of manganese in Mn_3O_4 [602]. The structure of this stationary surface layer differs, however, from that in Mn_3O_4 .

The decomposition of hydrogen peroxide on thin layers of platinum-supported manganese oxides was studied in the stationary and non-stationary regions [603]. The catalytic activities and the electrode potentials of the oxides were measured simultaneously. In the stationary region, the surface's oxidation state and structure were independent of the temperature, the hydrogen peroxide concentration, and of the presence of KCl and Mn^{2+} in the solution.

The catalytic activity of MnO_2 prepared by different methods was determined from the initial rate of decomposition of dilute solutions of H_2O_2 [604]. Experimental evidence showed that the presence of Mn^{3+} as MnOOH in the MnO_2 lattice is mainly responsible for the catalytic activity in non-stoichiometric manganese dioxide, where electron transfer between Mn^{4+} and Mn^{3+} ions can take place. The promoting effect of CuO in MnO_2 -CuO catalysts may be due the formation of surface CuMn_2O_4 through the exchange of Cu^{2+} on the hydrated manganese oxide surface.

Manganese sesquioxides with oxidation states between Mn^{+2} and Mn^{+4} have better catalytic activity than either pure MnO or MnO_2 . Sesquioxides can be prepared by partial reduction of MnO_2 with hydrazine [605].

The catalytic decomposition rates of hydrogen peroxide solutions in contact with 12 different MnO_2 samples followed a similar order to those of the reduction of MnO_2 , also dependent on the rate of proton diffusion in the crystal lattice [606].

The pyrolysis and calcination of ammonium permanganate NH_4MnO_4 gives finely distributed manganese oxide, which is a very active catalyst for the decomposition of H_2O_2 [607]. The catalytic decomposition of H_2O_2 was investigated on various calcination products of NH_4MnO_4 , prepared in the temperature range 423–1023 K (150–750°C). Correlating reaction rates with physicochemical characteristics of the catalysts, it was deduced that the most active sites for the heterogeneous reaction in aqueous solution were those involving a mobile-electron within the Mn^{4+} - Mn^{3+} coupling.

For several decades, manganese dioxide catalysts were prepared by decomposition of potassium permanganate or sodium permanganate or manganese salts of organic, combustible acids deposited on a porous carrier. The interference by sodium or potassium was usually ignored. Thus, it was a significant improvement when a new, much cleaner method for depositing high surface area manganese dioxide by decomposition of permanganic acid was developed [608]. Unsupported and ψ -alumina supported MnO_x catalysts (1–10 mass-% Mn) were prepared from aqueous solutions of HMnO_4 and compared with nitrate based samples. They were

characterized by XRD, X-ray photoelectron spectroscopy (XPS), BET surface area, oxygen storage capacity, and by their catalytic behavior. The unsupported oxide was amorphous at 573 K (300 °C) with a high surface area (45 m²/g) and transformed to α -Mn₂O₃ when heated to below 873 K (600 °C). The supported samples showed high dispersion that correlated well with high catalytic activity and the absence of detectable crystalline phases.

β -manganese dioxide doped with 0.1 M chromium(VI) trioxide was sintered at 523, 773, 1023, and 1273 K (250, 500, 750, and 1000 °C), and the products were characterized by XRD [609]. The catalytic activity of the catalysts for H₂O₂ decomposition was tested in aqueous and alkaline solutions. XRD revealed that the addition of 0.1 M CrO₃ stabilized the β -MnO₂ crystalline form at 773 K (500 °C). The transformation of β -MnO₂ into cubic Mn₂O₃ was detected after heating at 1023 K (750 °C). At 1273 K (1000 °C) a crystalline Mn₃O₄ was produced. The addition of 0.1 M CrO₃ to β -MnO₂ decreased the catalytic activity for H₂O₂ decomposition in aqueous solution. The activity of the mixed catalysts was higher than that of pure β -MnO₂.

Unsupported and alumina supported manganese oxide catalysts were evaluated by decomposition of H₂O₂ in dilute aqueous solutions at 303 K (30 °C) [610]. Three precursors were used to prepare the various series of unsupported and supported manganese oxide catalysts: **(1)** manganese(II) nitrate, **(2)** ammonium permanganate NH₄MnO₄, and **(3)** manganese(II) hydroxide obtained by slow addition of Mn(NO₃)₂ solution to aqueous ammonia followed by filtration and drying. In the case of manganese nitrate and ammonium permanganate, the supported catalysts were obtained by impregnation from aqueous solutions of various concentrations. The samples were subsequently dried and then calcined at 423, 573, or 873 K (150, 300, or 600 °C) in air. The catalysts were characterized by differential thermal analysis (DTA), XRD, XPS, BET, temperature-programmed reduction (TPR) under hydrogen, and by their oxygen storage capacity as indicated by their ability to oxidize repetitive pulses of carbon monoxide ("gas titration") at 573 K (300 °C) until the carbon monoxide passed through unchanged. There was a good correlation between H₂O₂ decomposition activity and oxygen storage capacity. The most active catalysts were those derived from decomposition of ammonium permanganate after calcination at 573 or 873 K (300 or 600 °C).

The activity of manganese oxide octahedral molecular sieve catalysts doped and undoped with transition metals (Fe, Ni, Cu, Co) were tested with dilute H₂O₂ solutions [611]. These materials were more active than plain MnO₂, but they do not have the temperature resistance required for operation with higher HTP concentrations in rocket engines.

The decomposition activities of a range of Mn₂O₃-based composite catalysts were measured in an attempt to define the surface attributes of the H₂O₂ decomposition activity of manganese oxides [612]. It was shown that the decomposition activity of Mn₂O₃ can be promoted by transition metal oxide additives that are capable of the formation of microcrystallites of mixed or composite oxide phases with the host oxide and exposing them on the surface of intimately coupled ionic species of different

oxidation states. Of particular interest are additives of NiO , BiO_x , and CuO_x , which generate $\text{Mn}^{3+}/\text{Mn}^{4+}$ couples at the surface, as well as $\text{Ni}^{2+}/\text{Ni}^{3+}$ couples in the case of the $\text{Ni}_x\text{Mn}_y\text{O}_3$ catalyst. A reaction mechanism including the hydroperoxide/superoxide anion was proposed. The decomposition of dilute hydrogen peroxide on manganese(III) oxide at pH 7 was represented by a pseudo first-order model. In addition, both H_2O_2 decomposition and the production of anion were accelerated in alkaline solution. Manganese ion dissolved into solution was negligible in neutral and alkaline conditions, but it greatly increased in acidic conditions. These bulk and surface compositions generate the optimal electron availability of the bulk and electron-mobile environment at the surface and facilitate the redox pathway of H_2O_2 decomposition. The activation energy of H_2O_2 decomposition on the nickel-promoted catalyst NiMnO_x was 11.6 kJ/mol, which was much lower than that of manganese oxide alone (77.1 kJ/mol).

One-inch diameter samples of catalyst-coated Celcor monoliths were immersed in hydrogen peroxide with a concentration of <10 mass-% H_2O_2 and allowed to react in a controlled environment to measure their activity [502]. The carrier was coated with KMnO_4 or NaMnO_4 with or without additional KOH or NaOH as promoters from an aqueous solution and calcined at 573 K (300 °C) in air for 8 h, and this cycle was repeated once or twice. The best performing samples were later tested in a 1-in. D $\times$ 5 in. L flanged reactor with HTP. Monolith samples with 11000 cells per square inch (cps) gave much better results than samples with coarse 400 cps. The paper fails to report the HTP concentration used for the reactor tests where a decomposition temperature of 1023 K (750 °C) was achieved, but one must assume that the same HTP as for the single drop tests with a pipet was used (95–98% H_2O_2). The work continued with characterization of additional substrates for the catalytic decomposition of hydrogen peroxide [613].

The application of manganese oxides as catalysts for the adiabatic decomposition of concentrated solutions of H_2O_2 suffers from particle fragmentation, solubilization, and active metal elution due to the strong solvating and erosion power of the H_2O_2 solutions under high-temperature conditions [614].

H_2O_2 decomposition over different manganese oxide-based perovskites ($\text{Ln}_{1-x}\text{A}_x\text{MnO}_3$; Ln = La or Nd and A = K or Sr and $x = 0.0\text{--}0.4$) was measured [615]. XRD and XPS analyses showed the presence of the single crystalline perovskite phases with an enrichment of the surface with potassium for the $\text{Ln}_{1-x}\text{K}_x\text{MnO}_3$ samples. δ -oxygen non-stoichiometries of the perovskites were studied by chemical analyses, temperature programmed reduction (TPR), and oxygen desorption (TPD) experiments. The results suggested that the catalytic H_2O_2 decomposition over these perovskites is not determined by the surface K, Ln, and Mn concentration nor by the $\text{Mn}^{4+}/\text{Mn}^{3+}$ surface ratio. On the other hand, a good correlation between the catalytic H_2O_2 decomposition and the δ -oxygen non-stoichiometries was found, especially for La perovskites. A suprafacial mechanism was suggested, where the oxygen vacancies participate in the H_2O_2 decomposition.

A series of manganese oxides loaded on to an active alumina support was prepared by impregnation methods, and the kinetics of H_2O_2 decomposition in an aqueous medium were studied in the presence of these oxides [616]. The amount of manganese, expressed as Mn_2O_3 , varied between 3.7 and 55.3 mass-%. The catalytic activities increased initially as the amount of manganese present increased, attaining a maximum value at 13.4 mass-% Mn_2O_3 and then decreased again. The apparent activation energy for H_2O_2 decomposition conducted over these catalysts was unaffected by a change in the amount of manganese present. Doping with lithium did not improve the activity for decomposition of H_2O_2 but accelerated the sintering and loss of surface area [617]. The catalytic activities and the values of BET surface area of pure and doped mixed oxides were found to decrease by increasing the amount of Li_2O present. It is common practice to prepare supported manganese oxide catalysts by impregnating carriers with permanganates and then decompose them [618].

A doping with Zn ions was found to improve the activity of $\text{MnO}/\text{Al}_2\text{O}_3$ calcined at 873 K [619]. The catalytic activities of the pure and doped mixed solids increased with increasing the reaction temperature and calcination temperature up to 873 K (600 °C), whereas no measurable activity was observed for catalysts calcined at 1273 K.

The effect of ferric and manganese oxide dopants on thermal and physicochemical properties of Mn-oxides/ Al_2O_3 and $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$ systems was studied [620]. The pure and doped mixed solids were prepared by an impregnation method, then thermally treated at 673–1273 K (400–1000 °C). Pyrolysis of pure and doped mixed solids was investigated via TGA and differential thermogravimetry (DTG) techniques. The products were characterized by XRD. The catalytic behavior of the thermal products was tested using the decomposition of H_2O_2 reaction. The activity of manganese oxide catalysts can be increased by doping with aliovalent metals, essentially creating ternary oxides, perovskite-like compositions. Iron(III) ion additives were found to promote the H_2O_2 decomposition activity of $\text{Mn}_2\text{O}_3/\text{Al}_2\text{O}_3$ up to a certain loading level, whereas Mn^{3+} ion additives to $\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$ continued to progressively increase the activity with the loading level.

Doping with La^{3+} ions has been found to increase the activity of $\text{MnO}/\text{Al}_2\text{O}_3$ or $\text{NiO}/\text{Al}_2\text{O}_3$ in proportion to the amount of dopant [621]. The effects of doping of Al_2O_3 -supported nickel and manganese oxides with La_2O_3 on their surface and catalytic properties were investigated using the oxidation of CO by O_2 at 423–473 K (150–200 °C), and the decomposition of H_2O_2 at 303–353 K (30–50 °C). The dopant concentration was varied between 1.0 and 6.0 mol-%. La_2O_3 -doping of alumina-supported metal oxides increased their catalytic activities towards CO-oxidation by O_2 and H_2O_2 decomposition to an extent proportional to the amount of dopant added. The doping process did not modify the activation energy of the catalyzed reaction but increased the concentration of catalytically active constituents taking part in the catalytic processes without changing their energetic nature.

Catalysts containing 2, 5, 7, or 10 mass-% MnO_2 supported on TiO_2 were prepared by impregnation of a high surface area TiO_2 with $\text{Mn}(\text{CH}_3\text{COO})_2 \times 4\text{H}_2\text{O}$ solutions and

examined for H_2O_2 decomposition activity [622, 623]. Samples were calcined at 773 K (500 °C) in air. XRD, SEM micrographs, and BET surface area measurements gave evidence of a uniform distribution of the active phase on the support surface and of the absence of segregated manganese oxide phases. Temperature programmed reduction measurements showed the presence of different Mn oxides species formed by interaction between the active phase and the support surface, besides MnO_2 . Catalytic activity tests were performed in a batch reactor with 50 or 70 mass-% H_2O_2 solutions. Catalytic activity was very high at the beginning of the tests and decreased with time, reaching a final constant value that increased with manganese content. Kinetic constants, evaluated assuming a first-order reaction rate, were comparable or higher than those of similar unsupported manganese-based catalysts. An optimal MnO_2 content was found, corresponding to the quite complete surface monolayer coverage.

Additional catalysts were prepared by deposition of 5–10% MnO_2 on partially stabilized ZrO_2 and totally stabilized ZrO_2 , commercial cordierite monolithic samples and tested for activity with 60% H_2O_2 [624]. The zirconia was stabilized with a mixture of MgO , CaO , and Y_2O_3 . Off-the-shelf Mn_2O_3 powder (30 m^2/g) showed negligible activity, while MnO_2 powder (53 m^2/g) showed high activity, suggesting that the catalytic H_2O_2 decomposition mechanism depends on the availability of Mn^{4+} ions at the surface. The kinetic rate constant of MnO_2 powder was an order of magnitude higher than that of supported MnO_2 . Catalytic activity increased with increasing Mn content; see also [625].

A new preparation method has been developed to produce homogeneous coatings of manganese compounds on alumina-coated monoliths by redox deposition-precipitation using acetone as solvent [626]. The deposition is produced by reduction of manganese(II) permanganate with ethanol. The Lewis acid sites on the alumina catalyze this reaction. Thus, the precipitation preferentially takes place on the surface of the monolith and not in the bulk of the solution. Monoliths prepared by this method are very active for the decomposition of H_2O_2 and the complete oxidation of oxygenated volatile organic compounds (VOCs). The active material on these monoliths consists of a mixture of complex phases including aluminum oxide, sulfated alumina, potassium sulfate, and manganese oxide.

Up to now, the development of catalysts for H_2O_2 decomposition has been a strictly empirical effort [as is (was) the development of any catalyst, which until recently was considered a “black art”]. Based on the observations of the activity of manganese oxides in the decomposition of H_2O_2 , theories have been proposed trying to explain the mechanism that takes place on the surface of metal oxide catalysts. A good summary of such theoretical approaches is provided in [627].

Two different catalysts have been prepared, characterized, and evaluated for the catalytic decomposition of 70% H_2O_2 for ignition of a bipropellant rocket engine using ethanol as the fuel [628, 629]. The catalyst substrate was a commercial mullite ceramic in the shape of honeycomb monoliths. Three different washcoating procedures were compared with the aim to allow a good anchorage of the active phase precursors: sil-

ver nitrate or sodium permanganate. For the silver catalysts, XRD indicated the presence of mullite, corundum, and metallic silver phases. After firing, a loss of silver was evidenced as well as the formation of silver oxide, depending on the washcoating procedure. Manganese oxide-based samples exhibited a better activity than silver-based catalysts and could survive the endurance test of 100 min in a rocket engine.

The decomposition of hydrogen peroxide on manganese(IV) oxide at pH 7 can be represented by a pseudo first-order model [594]. The maximum value of the observed first-order rates constant (k_{obs}) was 0.741 min^{-1} at a $[\text{H}_2\text{O}_2]/[\text{MnO}_2]$ ratio of 11.8. The average pseudo first-order rate constant ($k \text{ MnO}_2$) was $0.025 (\text{min mM})^{-1}$ when $[\text{H}_2\text{O}_2]/[\text{MnO}_2]$ ranged from 39.2 to 11.8. When $[\text{H}_2\text{O}_2]/[\text{MnO}_2]$ was 3.92, the rate constant ($k \text{ MnO}_2$) was $0.061 (\text{min mM})^{-1}$ at its maximum. Oxygen production showed that the initial rates increased with decreasing $[\text{H}_2\text{O}_2]/[\text{MnO}_2]$, and the actual amount of oxygen was slightly less than the theoretical stoichiometric value (0.5) in most experiments. The mechanism most likely includes propagation reactions with intermediates such as hydroperoxide/superoxide anions in solution. Both H_2O_2 decomposition and the production of anions were accelerated in alkaline solution.

Highly ordered mesoporous $\alpha\text{-Mn}_2\text{O}_3$ with well-defined mesopores, high surface area, and high oxygen vacancy exhibited excellent catalytic activity toward H_2O_2 decomposition at low temperatures [630].

The effect of catalyst support on the performance of monopropellant thrusters was investigated using three different support materials (monolith honeycombs, 1/8-in. alumina pellets and 16–20 mesh alumina granules) [631]. A reference catalyst ($\text{Na}_{0.2}\text{MnO}_2$) was coated on both catalyst supports and reacted with 90 mass-% hydrogen peroxide. Alumina sol was prepared from commercial alumina (Disperal® P2 by Sasol Company). The washcoat layer was dried and calcined ($393 \text{ K} = 120^\circ\text{C}$, 1 h and $773 \text{ K} = 500^\circ\text{C}$, 2 h) after it was coated on the monolith support. The washcoat layer had $260 \text{ m}^2/\text{g}$ specific surface area, $0.47 \text{ cm}^3/\text{g}$ pore volume, and 6.9 nm average pore size after calcination. The washcoated monolith support was loaded with $\text{Na}_{0.2}\text{MnO}_2$ by wet impregnation using NaMnO_4 solution as the precursor. The support was then dried ($323 \text{ K} = 50^\circ\text{C}$, 24 h) and calcined ($773 \text{ K} = 500^\circ\text{C}$, 2 h). The sodium ions were washed out with water, and the catalyst-loaded monolith was finally calcined ($1023 \text{ K} = 750^\circ\text{C}$, 2 h). The procedure for activating the pellet catalyst carrier was identical to that used for the monolith bed in all steps, except that it did not involve the washcoating step. The performance of two thrusters of different sizes with each thruster using either monolith honeycomb or alumina pellets as the catalyst bed was evaluated by measuring the product-gas temperature at the downstream end of the catalyst bed and the pressure of the gas at the inlet and outlet of the catalyst bed with constant propellant feed pressure. Under the given test conditions, the performance of the thrusters was better when using alumina pellets as the catalyst support than when using monolith honeycombs. Since the monolith support was less reactive than the pellets, pressure buildup in the former case was relatively small. Consequently, the chamber pressure and temperature were

lower when using the monolith support than when using the pelletized support. The pressure drop across the catalyst bed was moderate in both cases (0.02–0.1 bar in the case of a monolith and 0.3–0.7 bar in the case of a pellet catalyst).

A lead-promoted $\text{MnO}_2/\text{Al}_2\text{O}_3$ catalyst was more active with 90% HTP and less prone to chugging than a lead-free $\text{MnO}_2/\text{Al}_2\text{O}_3$ catalyst when tested in three reactors with different aspect ratios [632]. Al_2O_3 pellets of 1/8 in. (Alfa Aesar) with a BET surface of $255 \text{ m}^2/\text{g}$ were crushed, sifted to 10–16 mesh (1.18–2.0 mm) and 16–20 mesh (0.85–1.18 mm), and soaked with NaMnO_4 and $\text{Pb}(\text{NO}_3)_2$ solutions as precursor for MnO_2 and PbO , respectively, so that the atomic ratio of $\text{Mn}:\text{Pb}$ was 1:1. The catalyst was dried (95°C for 12 h) and calcined ($773 \text{ K} = 500^\circ\text{C}$ for 4 h). After calcination, the catalyst was washed with water to remove Na ions and impurities and dried ($368 \text{ K} = 95^\circ\text{C}$ for 12 h) again.

Manganese oxide coated monolithic catalysts were tested first with H_2O_2 vapor in the laboratory in a plug-flow reactor and then in a bolt-up flanged reactor on the rocket test stand [633]. The catalyst active phase was deposited on yttria-stabilized zirconia supports by: (a) soaking the support in manganese acetate $(\text{CH}_3\text{COO})_2\text{Mn}\cdot 4\text{H}_2\text{O}$ solution with vacuum impregnation, (b) drying, and (c) calcination. These steps can be repeated, typically five times. Whatever the specific preparation procedure, no wash-coat layer, traditionally used to increase the catalyst surface area, was applied in this study. Two different support configurations were tested: **(1)** tubes with an ID of 6 mm, an OD of 14 mm, and two different lengths (30 or 60 mm); and **(2)** honeycombs, with an OD of 13 mm, a cell density of 400 cells per square inch, and two different lengths (30 or 60 mm). A plug-flow reactor that carried H_2O_2 vapor in a helium stream was used to evaluate different catalysts. For this test, hydrogen peroxide (Propulse™ 875, nominal concentration 87.5 mass-%) was diluted to 50 mass-% and fed to the evaporator/reactor through a pump. The Pyrex® glass reactor can be divided into three zones:

- The preheating zone (135 mm L $\times$ 6 mm D) allows full vaporization of the solution, which mixes with helium.
- The catalytic zone (80 mm L $\times$ 19 mm D) has a larger diameter to allow catalyst insertion.
- The reaction products zone (175 mm L $\times$ 6 mm D).

At the exit of the reactor there was a condenser, to capture water vapor and any undecomposed hydrogen peroxide. The stream of helium and oxygen was then fed to a thermoconductivity detector to measure the hydrogen peroxide conversion. The best performing catalysts were then tested in a flanged heavy-duty stainless-steel reactor. The injection plate was made by laser-drilling 270 cylindrical holes of 0.1-mm diameter each. The bed length could be varied by choosing different cylindrical sections, 30 or 60 mm long. The reactor operated at flow rates of 6 to 10 g/s, and the chamber pressure was 0.3–0.6 MPa (3–6 bar). c^* efficiency decreased rapidly as soon as flow rates approached 7 g/s, indicating beginning flooding. While flooding is very detrimental for monopropellant thrusters, it may be tolerable for a reactor that is intended as an

igniter for a hybrid motor (as long as the decomposition products are hot enough to ignite the fuel).

Manganese-yttrium-zirconium mixed oxide nanocomposites with three different Mn loadings (5, 15, and 30 mass-%) were prepared by sol-gel synthesis and tested as catalysts for H_2O_2 decomposition in the liquid phase [634]. Their catalytic activity was higher than that of previously studied Mn/Zr oxide systems prepared by impregnation with manganese salts. Mesoporous materials with high surface area values (70–100 m^2/g) were obtained by annealing in air at 823 K (550 °C). They were amorphous or contained nanocrystals of the tetragonal ZrO_2 phase (T- ZrO_2) depending on the Mn amount and exhibited Mn species with oxidation state higher than 2 as confirmed by temperature-programmed reduction under hydrogen. The decrease of catalytic activity with time was blamed on leaching of a limited fraction (up to 15%) of Mn into the $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ solution.

Hydrogen peroxide monopropellant thrusters with manganese dioxide catalyst require preheating the catalyst bed for efficient operation in a space environment. Preheating requirements of 90 mass-% hydrogen peroxide in a monopropellant thruster with manganese dioxide catalyst were tested in a 50-N vacuum thrust class monopropellant thruster [635]. The preheating temperature was increased from 323 to 523 K (50 °C to 250 °C) in increments of 50 °C, and a test in cold start was included as a control group. The results indicate that a significant improvement in pressure rise time and avoidance of pressure instability was observed until the preheating temperature reached 423 K (150 °C). However, there were no noteworthy improvements when further increasing the preheating temperature beyond 423 K (150 °C).

Oxides of Group 8 Elements (Fe, Ru, Os)

Rust is present everywhere, and it is an active catalyst for decomposition of hydrogen peroxide, often in unwanted situations where rust-catalyzed decomposition may lead to accidents.

Iron(III) oxide catalysts are used for many industrial processes, and it helps to better understand the mechanisms that determine Fe_2O_3 catalyst activity and selectivity for those reactions. The decomposition of hydrogen peroxide is a very simple reaction (compared to some of the industrial multi-component reacting mixtures), and it has been used as a model reaction to study Fe_2O_3 catalysts. Although various shapes of Fe_2O_3 (and Fe_3O_4) catalysts are commercially available, there is little information about their use as catalysts in H_2O_2 monopropellant rocket engines.

The Fenton-type Fe(II) ion catalyzed reaction of hydrogen peroxide that is used for wastewater treatment requires acidic pH and Fe in a soluble form. It is generally accepted that lower pH values (2–4) are favorable for classical Fenton-like reactions performed with soluble Fe(II) homogeneous catalysts, yet two disadvantages accompanying the reactions are the acidic environment itself and the necessary separation of the dissolved iron from the reactive solution after process completion. For environ-

mental cleanup applications it would be desirable to develop an Fe-catalyst that operates near neutral pH and is heterogeneous, so that it will settle in a settling pond and can be reused after the cleanup is complete, and all organics are destroyed. With heterogeneous iron catalysts, the acidic environment should be avoided because leaching of iron oxides can cause a loss in catalytic activity. The highest rate constants so far achieved for iron oxides were reported for poorly ordered ferrihydrite and porous goethite (α -FeOOH) [636].

A comparative study of the catalytic efficiency in the decomposition reaction of hydrogen peroxide using different iron(III) oxides showed that the highest activity was achieved with amorphous ferrihydrite possessing the largest surface area, followed by crystalline oxides needlelike goethite and platelike hematite with the lowest surface area [637]. The rate constant observed for ferrihydrite was two orders of magnitude higher than for the other two iron oxides. However, when normalized with the surface area, the differences in the rate constants measured became far less significant.

Various iron(III) oxide catalysts were prepared by controlled decomposition of iron(II) oxalate dihydrate, $\text{FeC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ in air at the minimum conversion temperature of 448 K (175 °C), yielding amorphous Fe_2O_3 nanoparticles. The catalytic efficiency of the synthesized nanoparticles was tested by measuring the rate of decomposition of hydrogen peroxide [638]. The kinetic data obtained gave an unconventional non-monotone dependence of the rate constant on the surface area of the samples. The amorphous nanopowder with the largest surface area of $401 \text{ m}^2/\text{g}$ revealed the lowest catalytic efficiency, while the highest rates were achieved with samples having a significantly lower surface area, $337 \text{ m}^2/\text{g}$, exhibiting a prevailing content of crystalline α - Fe_2O_3 phase. The rate constant obtained, $26.4 \times 10^{-3} \text{ min}^{-1} (\text{g/L})^{-1}$, is one of the highest values published. The observed rare catalytic phenomenon, where the particle crystallinity prevails over the surface area effects, was unexpected. The unique behavior of iron(III) oxide nanoparticles, the catalytic efficiency of which is strongly determined by the crystallinity of the particles rather than by their surface area, supports the theory of local increase in catalytic activity with particle crystallinity and the general effect of the “surface quality” prevailing over the commonly accepted key role of a large surface area.

If colloidal or nanosized iron(III) oxide could be permanently suspended in fuels for H_2O_2 bipropellant rocket engines, it might be possible to hypergolize fuels that otherwise would not ignite when they come in contact with H_2O_2 .

Iron(II) oxalate dihydrate can be used as a readily decomposable substance for the controlled synthesis of nanosized iron(III) oxides. The polymorphous composition, particle size and surface area of these iron oxide nanoparticles were controlled by varying the reaction temperature between 458 and 773 K (185 and 500 °C). As-prepared samples were characterized by XRD, Mössbauer spectroscopy, BET surface area, and TEM and tested as heterogeneous catalysts in hydrogen peroxide decomposition [639]. The catalytic data demonstrated that the crystal structure of iron(III) oxide (i.e., the relative contents of maghemite and hematite) does not influence the rate of hydrogen

peroxide decomposition. However, the rate constant increased monotonously with increasing sample surface area (and decreasing thermolysis temperature), reaching a maximum of $27 \times 10^{-3} \text{ min}^{-1}(\text{g/L})^{-1}$ for the sample with a surface area of $285 \text{ m}^2/\text{g}$.

Most environmental waters contain suspended iron hydroxides in one form or another. These small amounts of iron hydroxides are enough to affect the survival rate of hydrogen peroxide that has formed as the result of sunlight illumination or biological activity. The same catalysts enhance the ability of hydrogen peroxide to destroy organics in wastewater. The heterogeneous catalytic reaction of H_2O_2 with iron oxides or hydroxides is an important reaction for the environment since both H_2O_2 and iron oxides and hydroxides are common constituents of natural and atmospheric waters. Three ferrihydrites were prepared by different procedures. The heterogeneous catalytic reaction of H_2O_2 with three ferrihydrites in aqueous solution demonstrated that the apparent reaction rate was affected by the preparation procedure of ferrihydrite besides pH, temperature, and the dose of catalyst [640]. Depending on the method of preparing the iron(III) hydroxide, the activation energy of the decomposition reaction of H_2O_2 was between 59 and 76 kJ/mol.

Oxides of Group 9 Elements (Co, Rh, Ir)

Oxides of cobalt, nickel, and copper, alone and in mixtures, were tested as catalysts for decomposing hydrogen peroxide [641]. For the individual oxide, equimolar quantities of a cobalt oxide, CuO , and Ni_3O_4 gave decomposition rates in the respective ratios 0.013:1.20:0.029. Various ternary and binary mixtures were studied, but only those with the compositions 80 Co:20 Ni or 80 Co:15 Ni:5 Cu were more active than the cobalt oxide alone.

The rate of decomposition of hydrogen peroxide in the presence of cobalt(III) oxide was first order but tended toward second order at low concentrations [642]. The order also increased with temperature. The suggested mechanism, a reduction-oxidation cycle, is like that for the reaction on MnO_2 catalysts.

Catalysts for decomposition of hydrogen peroxide have been developed based on cobalt and molybdenum oxides and their binary compositions supported on aluminum oxide [643]. Pure and ZnO-doped cobalt(II,III) sesquioxide catalysts were prepared by thermal decomposition in air at 673–973 K (400–700 °C) of pure basic cobalt(II) carbonate that had been treated with different amounts of zinc nitrate (0.46–2.25 mass-% ZnO) [644]. XRD powder diffractometry and BET surface area analysis of nitrogen adsorption isotherms investigated the crystalline bulk structure and the surface area of pure and doped samples, respectively. The hydrogen peroxide decomposition activity was determined by oxygen gasometry of the reaction kinetics at 293–313 K (20–40 °C). The results showed that the treatment of Co_3O_4 with ZnO at 673–973 K (400–700 °C) brought about a significant increase in the specific surface area of cobalt(II,III) oxide. The catalytic activity of cobalt(II,III) oxide for H_2O_2 decomposition was considerably increased by doping with ZnO.

Oxides of Group 10 Elements (Ni, Pd, Pt)

Active H_2O_2 decomposition catalysts that were tested in an activity test apparatus and in a rocket engine with 91% HTP were prepared by impregnating high surface area alumina with a solution of AgNO_3 and $\text{Ni}(\text{NO}_3)_2$, drying, and calcining [645]. The maximum activity was achieved with catalysts that contained silver and nickel in an atomic ratio of 1:9. In a side-by-side test in a rocket engine with samarium oxide activated silver screen and the AgO/NiO catalyst, the AgO/NiO catalyst was able to start the engine at 277 K (40 °F), while the silver catalyst flooded. Of the steady-state chamber pressure 90% was attained within 200 to 300 ms.

Nickel oxide was prepared by decomposing and calcining $\text{Ni}(\text{NO}_3)_2$ and used as catalyst for the decomposition of hydrogen peroxide vapor generated from a 99.9% H_2O_2 supply [646]. The activation energy of H_2O_2 vapor decomposition on a nickel oxide catalyst was $54 \pm 2 \text{ kJ/mol}$ ($13.0 \pm 0.5 \text{ kcal/mol}$).

A study of the vapor phase decomposition catalyzed by nickel oxide single crystals was conducted in an isothermal flow reactor [647]. Catalyst pretreatment consisted of annealing the crystals at various temperatures and in several atmospheres. This produced crystals with defects and non-stoichiometric compositions. The catalytic activity was characterized by the amount of decomposition per unit surface area. The kinetic parameters were compared with the electrical characteristics of single crystals, and it was found that the maximum catalytic activity occurred with a pretreatment at 1000 °C. As the calculated nickel vacancy concentration increased, the catalytic activity first increased then began to decrease.

A similar effect was also observed with other oxide catalysts. Preirradiation created crystal defects in the crystal structure of metal oxides [648]; see also [649].

Preirradiation with γ -rays may allow the formation of more active (crystal defect) sites in nickel(II) oxide or mixed nickel/silver oxides when tested as catalysts for the decomposition of hydrogen peroxide [650–653]. The H_2O_2 decomposition activity of samples containing 0–91 mass-% NiO is determined by the catalytic efficiency of the silver component present in the catalyst, and this efficiency seems to be connected with the surface concentration of Ag^+ ions. The γ -irradiation (dose 10 kGy) of samples containing an excess of silver lead to a lower catalytic activity, but irradiation of samples with a higher content of nickel oxide increased their activity. Irradiation of catalysts with fast neutrons appreciably decreased their activity, irrespective of their composition, while irradiation with β -radiation (dose 5.6 MGy) had no effect on their activity.

Oxides of Group 14 Elements (Si, Ge, Sn, Pb)

In this group of metal oxides, tin oxide predominates as a stabilizer, not as a catalyst for H_2O_2 decomposition. Silicon dioxide in the form of quartz is one of the most inert and non-catalytic materials in which to store H_2O_2 or conduct experiments in quartz vessels. Lead oxides have low melting points and are rarely used as catalysts, but con-

tamination by lead solder has been blamed for some of the more dramatic accidents involving H_2O_2 explosions. Therefore, lead and lead oxide must be examined. Lead solder is avoided in all systems where it might come in contact with H_2O_2 .

Freshly precipitated lead hydroxide is a very active catalyst for hydrogen peroxide decomposition. Lead hydroxide was more active than any of the other metal hydroxides studied.

It has been shown that surface reactions involving H_2O_2 may lead to interconversion of PbO_2 and PbO . Considerable changes of the rate and mechanism of catalytic decomposition of H_2O_2 are the result of changes in the composition of lead oxides and of the solution pH [654]. It was informative to correlate catalytic activity and potential poisoning by organic substances with the composition of PbO_2 and PbO . Since lead(II) oxide exists in yellow and red forms, and yellow PbO may pass into bright-orange Pb_3O_4 in the presence of oxygen, decomposition of H_2O_2 on different forms of lead oxides was investigated.

Lead oxide was used as a catalyst with 70% stabilized H_2O_2 for torpedo propulsion in the US for a few years after WW-II but was later replaced by silver-plated screens ("argent") or cobalt-plated brass screens ("irium").

If a mixture of lead powder with sulfur, selenium or tellurium powder, powdered lead oxide (litharge) and potassium permanganate is pressed together with a small amount (up to 1%) of asbestos or other refractory fibers as a binder, and the resulting pellets are ignited by means of a flame, a self-sustaining solid-state reaction gets started. This reaction leaves behind a hard pellet of very high catalytic activity for the decomposition of hydrogen peroxide, which can be used in combination with catalysts made from metallic silver, cobalt oxide, chromates, or a mixture of potassium permanganate and lead monoxide [655].

Mixed Metal Oxide Catalysts for Hydrogen Peroxide Decomposition

The catalytic activity of mixed metal oxides in the decomposition of H_2O_2 is not simply an additive effect of the two (or more) oxides from which they are synthesized, but there is a potentiating effect where the mixed oxides at very narrow mixture ratios are sometimes more than an order of magnitude more active than the oxides from which they are made. The mixed metal oxides are made from an ideal combination of a transition metal with multiple states of oxidation (preferably Mn, Fe, Co, Cr) and a ceramic metal oxide with a high melting point (such as Al_2O_3 , ZrO_2 , Y_2O_3 , La_2O_3). Depending on the ratio of transition metal oxide to ceramic oxide, these mixed oxides assume a variety of crystal structures that are often named after naturally occurring minerals. The mixed oxides do not necessarily have to be in stoichiometric proportions to each other to make good catalysts. On the contrary, non-stoichiometric proportions create a number of crystal defects that enhance catalytic activity by oxygen mobility. Sometimes traces of aliovalent metals are added to create specific types of crystal defects. Some of the mixed metal oxides have unique electric properties (normal electric conductivity, superconductivity, magnetism) that go hand-in-hand with catalytic ac-

tivity. Another group of mixed metal oxides has been developed for solid oxide fuel cells for the direct conversion of hydrocarbons and air to electricity. The same oxides are also being tested as potential hydrogen peroxide (and HAN or nitrous oxide) decomposition catalysts.

Traditionally, mixed metal oxides have been prepared by dry sintering (“shake and bake”, ceramic method) physical mixtures of the oxides in the proper proportions at very high temperatures until chemical bonding takes place. Sometimes, sintering aids are added to allow the forming of ceramic shapes at lower temperatures. The disadvantage of that method is that the resultant materials have very low active surface areas and may need to be activated with wash coats to obtain useful catalysts.

Another method of preparation of mixed metal oxides is coprecipitation from a mixture of the metal nitrates by slow addition of alkali and raising the pH. However, metal oxides of different metals precipitate at different pH, and the resulting precipitate may not be homogeneous. The preferred methods of precipitation are the so-called sol-gel methods, which result in coprecipitation of nanometer-sized crystals that can then be dried and sintered. Chemical bonding of the dried material is complete at much lower temperatures than with the “shake and bake” method, and, consequently, the resulting materials have a higher surface area. Compared with the conventional ceramic routes, such as coprecipitation, grafting, or impregnation, the sol-gel method exhibits many advantages, among them the low process temperature and a strict control of purity, composition, microstructure, and textural properties of the final material. Particularly for mixed-oxides this synthesis procedure allows one to obtain materials with a high dispersion of the active phase in the matrix on both molecular and nanometer scale.

A detailed study of the flow decomposition of hydrogen peroxide vapor on a wide range of XO/Y_2O_3 mixed metal oxides showed that mixed metal oxides are more active than the binary oxides they are derived from [656].

In Russia, mixed metal oxide catalysts were produced in quantity and flight-qualified for thrusters with hydrogen peroxide concentrations up to 95.5 mass-% H_2O_2 [534]. Catalysts with the designation K-83, K-85, K-86, or K-87 have been commercially produced by RSC Applied Chemistry since 1966 and are intended for decomposition of HTP of concentrations up to 95.5%. As of 2001, catalysts K-88, K-90, and K-95 were in an advanced development status and were intended for decomposition of HTP concentrations up to 100% H_2O_2 . The catalysts were characterized by liquid phase and vapor phase H_2O_2 decomposition activity and activation energies. Although catalyst K-85 provided initiation of HTP decomposition at temperatures down to 233 K (−40 °C), it was quickly destroyed during extended operation that resulted in increase of pressure drop of a catalyst bed and in decrease of the HTP flow rate. Therefore, catalyst K-85 was applied in a mixture with catalyst K-83, which is less active, but was more durable. Catalysts K-86, K-83, and K-85 were used in 75-, 100-, and 150-N thrusters. A cross section of one of these thrusters is shown in a figure in *Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide Monopropellants”. In catalyst beds for 12-

and 16-N thrusters, the catalysts K-86 and K-87 were used instead, which had smaller granule sizes. The catalyst K-86 assured completeness of HP decomposition. The catalyst K-87 was in the shape of tablets and, therefore, allowed packing of the catalyst by hand in a controlled manner. The catalyst K-86 was in the shape of disks with a diameter equal to the diameter of the catalyst bed. It was capable of complete decomposition of HP and was very durable. Design examples of thrusters using these catalysts are shown in *Encyclopedia of Monopropellants*, chapter "Hydrogen Peroxide Monopropellants".

The thermal decomposition under hydrogen of binary complex compounds (BCCs) consisting of complex cations and complex anions is a method for preparation of catalysts that also find use in Fischer-Tropsch synthesis, CO oxidation in automobile exhaust, and oxidative destruction of pollutants. The catalytic activity of binary metal catalyst samples that were obtained via the thermolysis of binary complex compounds (BCCs) in a hydrogen atmosphere for hydrogen peroxide decomposition was determined by measuring the rate constants and activation energies for the catalytic reaction [657]. The establishment of a correlation between catalytic activity, composition, specific surface area (S_{sp}), and particle size of the samples was attempted. Several conclusions were drawn about the decomposition of H_2O_2 on semiconducting oxides:

- (1) The rate-determining step is the emission of electrons from the surface of the catalyst.
- (2) The dependence of the reaction rate on specific surface area is negligible.

The rate constants and BET surface areas of 28 binary Cr, Co, Fe, Cu mixed metal oxide catalysts reduced under hydrogen at different temperatures between 573 and 1173 K (300 and 900 °C) for the decomposition of H_2O_2 were measured and their crystal structures determined by XRD.

Spinels

Two types of cobalt-iron spinel oxides $Co_xFe_{3-x}O_4$, ($0 \leq x \leq 3$) prepared by hydroxide or oxalate coprecipitation routes were studied in order to define the intrinsic and microstructural factors influencing the catalytic activity for heterogeneous H_2O_2 decomposition in alkaline solution [658]. The activity sequence in order of decreasing activity was found to be $x = 1.0 > 1.5 > 2.0 > 2.4 > 3.0 > 0.6 > 0.0$ based on diffusion-free activation energies for the decomposition reaction. This order agreed with results obtained by measuring the initial rates of H_2O_2 decomposition, provided that the rates were normalized for the area of reaction available at the catalyst surface. The activity order could be interpreted in terms of the electronic structure of cobalt-iron oxides, and a key factor was the presence of Co^{2+} ions on the octahedral lattice sites, which can initiate a cyclic electron transfer process (redox reaction) on the catalyst surface. The maximum activity and the lowest activation energy for the reaction occurred at $x = 1$ since the greatest availability of octahedral Co^{2+} occurred at this composition.

Cobalt-ferrite spinel oxides of the type $\text{Co}_x\text{Fe}_{3-x}\text{O}_4$, ($0 \leq x \leq 3$) were synthesized by coprecipitation [659]. Kinetic studies revealed pronounced activity of these oxides in the catalytic decomposition of hydrogen peroxide. The optimum activity of this decomposition reaction is at lattice composition of $x = 1.5$ in the spinel system. XRD and SEM results indicated that at $x = 1.5$, the Co^{++} ions are at the octahedral lattice sites of the ferrite support.

Some ferros spinels of the $\text{M}^{\text{II}}\text{Fe}^{\text{III}}_2\text{O}_4$ type act as catalysts for the decomposition of H_2O_2 . Their effectiveness is dependent on the composition of the catalyst. A set of ferrites of different composition ($\text{M}^{\text{II}} = \text{Mn, Co, Ni, Cu, Zn, Cd}$) was synthesized by coprecipitation and characterized by chemical analysis, XRD, and BET surface area measurements [660]. The catalytic activity decreased in the order $\text{MnFe}_2\text{O}_4 > \text{CoFe}_2\text{O}_4 > \text{CuFe}_2\text{O}_4 > \text{NiFe}_2\text{O}_4 > \text{CdFe}_2\text{O}_4 > \text{ZnFe}_2\text{O}_4$. The first in the list, MnFe_2O_4 , was much more effective than any of the others by a factor of 50–100 [661].

The effects of doping and thermal treatment on catalytic properties of pure iron(III) oxide solid were studied by means of thermal analyses (TG-DTG-DTA), XRD, BET analysis of nitrogen isotherms, and hydrogen peroxide decomposition activity measurements at 293–323 K (20–50 °C) [662]. A series of Co_3O_4 - Fe_2O_3 and Mn_2O_3 - Fe_2O_3 mixed oxides were prepared from cobalt nitrate, basic iron(II) carbonate, and manganese nitrate salts by an impregnation method. Both Co_3O_4 and Mn_2O_3 were used as dopants (0.25–4.00 mol-%) for pure Fe_2O_3 . The pure and doped solids were baked at 623, 823, 1023 or 1273 K (350, 550, 750, or 1000 °C). The solids baked at low temperature led to formation of free oxides in physical admixture. The doped solids calcined at high temperature resulted in the formation of ferrites (CoFe_2O_4 or MnFe_2O_4). The catalytic activity of pure Fe_2O_3 significantly increased with increasing the amount of cobalt or manganese oxides dopants. The observed increase in activity was attributed to increasing the concentration of catalytically active constituents and/or formation of new active sites. The measurement of activation energy of the catalytic reaction for pure and doped solids revealed that the doping process did not modify the energetic nature of the active sites involved in the catalyzed H_2O_2 decomposition reaction. While the catalytic activities of doped solids increased by increasing the calcination temperature from 623 to 823 K (350 to 550 °C), above that it significantly decreased with further increase of baking temperature up to 1023 K (750 °C). The progressive decrease in the activity was due to formation of inactive ferrite compounds and/or sintering processes.

Perovskites

The heterogeneous decomposition of hydrogen peroxide was studied in alkaline electrolytes on $\text{LaFe}_x\text{Ni}_{1-x}\text{O}_3$ perovskite-type oxides intended to be used as electrodes in fuel cells [663]. The reaction was found to be of first order in HO_2^- concentration. Maximum catalytic activity was found for $x = 0.25$. The optimum temperature of synthesis by the “shake and bake” method was between 873 and 973 K (600 °C and 700 °C), this being a compromise between a sufficiently high temperature to synthesize the per-

ovskite structure and a sufficiently low temperature to produce a high surface area catalyst with a low number of oxygen vacancies.

Lanthanide perovskite oxides can catalytically decompose hydrogen peroxide not only in rocket engines, but also in electrochemical sensors for analytical applications. The catalytic properties of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_{3-\delta}$ perovskites are due to their oxygen vacancies and are influenced by the oxide non-stoichiometry δ and increase with increasing non-stoichiometry, x [664].

$\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ ($0 < x < 0.8$) perovskite-type oxides were synthesized by the combined EDTA-citrate complexing method, characterized by XRD, and their catalytic activity for the decomposition of caustic 1.2-M hydrogen peroxide solution was investigated at 303, 308, and 313 K (30, 35, and 40 °C) [665]. Hydrogen peroxide decomposition was a first-order reaction on these catalysts. With the increase of Sr substitution, the catalytic activity increased accordingly, and $\text{La}_{0.2}\text{Sr}_{0.8}\text{MnO}_3$ was the most active catalyst tested. It was suggested that the active sites for hydrogen peroxide decomposition on $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ catalysts can be attributed to Mn^{4+} ions.

Supported perovskite catalysts were prepared by impregnating the $\gamma\text{-Al}_2\text{O}_3$ carrier (with a BET surface area of $176 \text{ m}^2/\text{g}$) with an aqueous solution containing appropriate amounts of $\text{La}(\text{NO}_3)_3$, $\text{Sr}(\text{NO}_3)_2$, and $\text{Mn}(\text{NO}_3)_2$, followed by drying at 393 K (120 °C) for 8 h and then calcined at 1023 K (750 °C) for 3 h in air [666]. A catalyst made by coating 25% $\text{La}_{0.6}\text{Sr}_{0.4}\text{MnO}_3$ on alumina was tested with 85% HTP in a 10-N thruster at a flow rate of 5 g/s. The first 10-s pulse looked good, but by the time the pulsing was repeated 19 times, the chamber pressure roughness had increased to a point that the reactor had to be shut off; see also [667].

A ceramic monolith was coated with 13% $\text{La}_{0.8}\text{Sr}_{0.2}\text{CoO}_3$ (Lanthanum Strontium Cobaltate = LSC) and performed well in the lower bed of a gas generator with 80% HTP [668, 669].

Perovskites were synthesized by thermal decomposition of metal citrate mixtures and tested as catalysts for decomposing hydrogen peroxide [670]. The ignition delaying times (IDT) of H_2O_2 were measured with 90 or 30% H_2O_2 on different wetted catalysts. The IDT depended more on the wetted level of the catalysts than on the chemical composition. The activity of catalysts depended on the chemical composition. The activity order (in order of increasing activity) was $\text{LaNiO}_3 < \text{LaCoO}_3 < \text{LaMnO}_3 < \text{LaMn}_{0.5}\text{Co}_{0.5}\text{O}_3 < \text{LaMn}_{0.8}\text{Co}_{0.2}\text{O}_3 < \text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{0.8}\text{Co}_{0.2}\text{O}_3$. To prepare a commercial catalyst, 30% $\text{La}_{0.7}\text{Sr}_{0.3}\text{Mn}_{0.8}\text{Co}_{0.2}\text{O}_3$ were supported on $\gamma\text{-Al}_2\text{O}_3$ microspheres. At high bed-loading (higher than $5 \text{ g} \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$) in a simulated rocket engine, the longevity of the supported catalyst was better than 4000 s.

The isomorphic substitution of Mn in the LaMnO_3 structure by different amounts of Fe and Mo to produce $\text{LaMn}_{1-x}\text{Fe}_x\text{O}_3$ and $\text{LaMn}_{0.1-x}\text{Fe}_{0.90}\text{Mo}_x\text{O}_3$ created active catalysts [671]. The Fe and Mo can vary their oxidation states, and this property can improve the catalytic activity in oxidation processes. These perovskites were characterized, and the catalytic activity was investigated using 7 mL of 2.9-M H_2O_2 (2.9 mol/L)

and 60 mg of catalyst. Fe addition decreased, and Mo improved the rate of H_2O_2 decomposition.

Perovskites of the type $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ are active catalysts for decomposition of hydrogen peroxide not only in rocket engines, but also in fuel cells [672]. Perovskite-type series of compounds $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ with different x were synthesized by a sol-gel method using chitosan as the gelling agent. The catalytic activity for hydrogen peroxide electroreduction in 3-*M* KOH at room temperature was evaluated by means of cyclic voltammetry and chronoamperometry. The effects of the annealing temperature and the ratio of La to Sr on catalytic performance was investigated. In this series of compounds, $\text{La}_{0.4}\text{Sr}_{0.6}\text{MnO}_3$ calcined at 650 °C exhibited the highest activity, which was comparable with Co_3O_4 .

$\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ ($x = 0.0, 0.2, 0.4$, and 0.6) perovskites were synthesized using the citrate gel method, characterized by TGA, DTA, XRD, SEM, and BET surface area, and their catalytic activities were examined for the hydrogen peroxide decomposition reaction [673]. The catalytic activity was improved with increasing calcium content in the catalyst, and it was suggested that factors such as δ -oxygen non-stoichiometry and shifting manganese average valence states were responsible for the catalytic activity of these materials.

Other Mixed Oxide Catalysts

Dry-mixed oxides were pressed into pellets at 33000 psi and sintered at up to 810 K (1000 °F) and tested by immersing a pellet in 10 mL of 98% H_2O_2 in a graduated cylinder and measuring the time required for complete consumption of the liquid [674, 675]. Mixed oxides $\text{BaO}/\text{Mn}_2\text{O}_3/\text{PbO}$ and $\text{BaO}/\text{Mn}_3\text{O}_4/\text{PbO}$ with low lead content showed good activity. Most of these pellets showed a rapid decline in activity with repeated testing.

Catalytic activities of two non-conducting cuprates ($\text{Ba}_2\text{Cu}_3\text{O}_5$, Y_2BaCuO_5) and a superconducting cuprate $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$, prepared by two different methods, were compared using H_2O_2 solutions [676]. The two non-conducting barium cuprates were found to be about two orders of magnitude more active than the superconducting perovskite-like $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$. First-order kinetics were observed for the catalyzed decomposition of H_2O_2 solution over the non-perovskite Y_2BaCuO_5 at the initial stages of the reaction, similarly to that of the superconducting perovskite catalyst. A tentative scheme of the possible catalytic reactions for the decomposition of H_2O_2 solution over the insulator Y_2BaCuO_5 indicated that electron transfer from the lone electron pairs in HOOH to the d-orbitals of copper is not a rate determining step of H_2O_2 decomposition on this catalyst.

A catalyst consisting of mixed manganese oxide-lead oxide supported on 18–30 mesh high surface area alumina granules has been developed in China [677]. In this catalyst, the lead oxide greatly promoted the activity of manganese oxide in the decomposition of hydrogen peroxide. Manganese and lead nitrates were dissolved in deionized water to obtain the impregnating solution. The catalysts with various mo-

lar ratios of $\text{MnO}_2:\text{PbO}$ were prepared by impregnating the alumina support with the solution, and the impregnated catalysts were dried, and then calcinated in air at 673–693 K (400–420 °C) for 5h. The total loading of the metal oxides was 10 mass-%. The catalyst activity was measured by a traditional gasometric method using 0.03 g catalyst mixed with 10 mL H_2O_2 ($d = 1.3336 \text{ g/cm}^3$). The other evaluation was done in a monopropellant rocket thruster. A catalyst with a $\text{MnO}_2:\text{PbO}$ mass ratio of 1:1 had the highest activity. The activity of the catalyst for hydrogen peroxide decomposition was attributed to the formation of a new phase, and this new phase was characterized by XRD, XPS, and TPR.

New catalysts for H_2O_2 decomposition based on manganese-yttrium-zirconium mixed oxide nanocomposites have been prepared by a sol-gel method [678]. Materials with different active metal loadings of the active phase were prepared in order to optimize the chemical composition of the material for maximum catalytic activity. A mixture of $\text{Zr}(\text{OC}_3\text{H}_7)_4$, $\text{YCl}_3 \cdot 6\text{H}_2\text{O}$, and $\text{Mn}(\text{NO}_3)_2 \cdot 5\text{H}_2\text{O}$ dissolved in isopropanol was slowly hydrolyzed by addition of water to form the sol and then the gel. Three compositions were made with different percentages of Mn (5, 15, and 30% Mn) with respect to 100 g of matrix, whose molar composition was $95\text{ZrO}_2 \cdot 5\text{Y}_2\text{O}_3$. Three annealing temperatures were chosen for the dried gels: 773, 973, and 1273 K (500, 700, and 1000 °C). The lower temperature is the minimum temperature at which it is possible to obtain complete decomposition of nitrate ions and elimination of the solvent and residual organics (stabilized gels). The higher temperature values were selected to force the crystallization of the samples. The activity of the finished catalysts was tested by measuring the rate of oxygen evolution in contact with 30–40% H_2O_2 in a stirred reactor. The 30% Mn catalyst with a BET surface area of $100 \text{ m}^2/\text{g}$ was the most active catalyst tested in this series.

Molecular sieves do not have the high-temperature capability required for H_2O_2 in rocket engines, but they can also decompose H_2O_2 in a fixed-bed reactor [679]. Tetrahedrally coordinated Ti in a titanasilicate molecular sieve was more active in H_2O_2 decomposition than octahedrally coordinated Ti.

4.10.2.10 Metal/Metal Oxide (Cermets) Catalysts for Hydrogen Peroxide Decomposition

Many metals are good catalysts for the decomposition of hydrogen peroxide, but their melting point is too low. Many metal oxides are good catalysts for the decomposition of hydrogen peroxide, but it is difficult to bond metal oxide powders together. If one melts them, they lose all surface area and most of their catalytic activity. Some sort of glue is needed to hold them together. Finely divided malleable metals like silver, copper, and their alloys can be pressed together with metal oxide powders and will provide cold-pressed bodies with some mechanical strength, which can be improved by further sintering. Such composites made from **ceramics** and **metals** are called “cermets”. Similar cermet materials have been used for other parts in rocket engines, such as nozzles or reentry heat shields.

Cosolidified silver/metal oxide mixed catalysts also called “cermet catalysts” showed significantly higher activity in the decomposition of concentrated H_2O_2 than that of silver metal alone [680]. The effect of discrete particles of catalytically inactive material, uniformly dispersed in a continuous phase of silver metal, upon the phenomenon of vapor binding at silver surfaces in contact with concentrated H_2O_2 was investigated. A method for producing the desired surface was developed to yield a cermet in which inactive material is uniformly distributed throughout the body of the “catalyst.” The behavior of such cermets toward concentrated H_2O_2 was followed by measuring oxygen evolution rates of semiadiabatic, atmospheric pressure reactions in a constant volume reactor. The cermets, prepared in pellet form, contained silica, silicon carbide, or copper oxide as the inert material. The startup activity of all cermets with concentrated H_2O_2 was better than that of pure silver and markedly higher than that shown by $\text{Sm}(\text{NO}_3)_3$ -treated silver surfaces. Reactivity with concentrated H_2O_2 per unit apparent silver surface area was as much as 20 times higher than that of consolidated silver.

Sintered pelletized compositions containing powdered silver and copper oxide are useful for decomposing hydrogen peroxide. The preferred catalyst contained 87 mass-% silver and 13% CuO [681].

A pelletized catalyst can be made by sintering 80 to 95% silver with 5 to 20% copper oxide [682]. No low-melting eutectic forms in the sintering step, in contrast to the pellets described in other patents where metallic copper is used. The pellets can be heat treated nearly to the melting point of silver. The preferred composition contained 91.3% Ag and 8.7% CuO . Copper(II) oxide is a relatively good catalyst even without being sintered with silver. Even inert ceramic oxides (other than copper(II) oxide) can be sintered with silver and still obtain a cermet catalyst with decent activity [683, 684]. Active silver powder can be mixed with inert ingredients, such as Al_2O_3 , SiO_2 , or SiC (all of which are stable up to the melting point of silver), and then pelletized. A typical catalyst contained 75% silver and 25% of inert material.

The sintering of metallic silver catalysts often causes incomplete decomposition at cold start and chamber pressure oscillations towards the end of their useful life. Chugging will induce flow instabilities in the feed system. It was shown that the addition of ceramic materials to silver increased the thermal resistance of catalyst beds [685]. These cermets are also called “composite silver catalysts”. By proper catalyst bed packing, it was possible to obtain excellent catalyst test results. The I_{sp} from a cold start was 104.9s, and I_{sp} during hot steady-state firings was 114.9s. The start transient was about 100 ms and 50 ms from cold and hot fire, respectively, which included the operating time of the solenoid valve. In continuation of this catalyst characterization, a 1-N thruster prototype using a combination of silver and ceramic cermet material as catalyst bed for hydrogen peroxide monopropellant decomposition was tested [686]. With a chamber pressure of 150 psi, the thrust was 0.7 N at atmospheric pressure, and the specific impulse was about 102s. The catalyst bed has been modi-

fied and tested over 4000 s using 90% H_2O_2 propellant. Repeatability demonstration, blow-down tests, and environmental tests were planned.

4.10.2.11 Other Catalysts for Hydrogen Peroxide Decomposition

The catalysts discussed here may not be suitable for rocket engines, but they illustrate the wide variety of compounds that will catalyze hydrogen peroxide decomposition, even in living systems. Hemoglobin-bound iron in blood platelets and other metals inserted into porphyrin complexes are active catalysts for the decomposition of hydrogen peroxide. The decomposition of hydrogen peroxide by four kinds of silica-supported Cu- and Co-porphyrins was measured by kinetic studies, and the reaction rates were expressed based on the kinetic data [687]. The rate differences with various metallo-porphyrins were explained by the different processes for the formation of intermediates.

Saliva contains peroxidase and catalase. Just spitting into a dilute solution of hydrogen peroxide will cause it to decompose, similar to peroxide processes happening during digestion, metabolism, and assimilation. One can notice this reaction when using dilute (<1%) H_2O_2 solutions as mouthwash and for gurgling. The enthalpy of decomposition of hydrogen peroxide by catalase has been determined calorimetrically in isotonic saline solutions at 25 °C [293].

It has been attempted to improve startup properties of HTP with marginal quality catalysts by dissolving “promoters” in the HTP. These promoters were usually organic peroxides which are known to be compatible with HTP. The data in the literature about purported benefits of dissolving promoters in HTP are not convincing and safety property testing is lacking. It was claimed that HTP made by an electrolytic process, which is free of organic residues, would decompose more slowly than HTP from an IPA or AO process. When organics were added to electrolytic grade HTP, it decomposed faster when in contact with silver wire catalyst and showed an increased rate of oxygen evolution, a faster rise in temperature, and improved starting at low temperatures as compared with hydrogen peroxide not containing the residue [688].

Colloidal and nano-size catalyst particles suspended in an emulsion have shown superior activity for the decomposition of hydrogen peroxide. In one example, Ag nanoparticles were prepared in tetraethylene glycol monododecyl ether/cyclohexane/ AgNO_3 microemulsions by reducing with excess NaBH_4 solution [689]. Then colloidal silica was added as a catalyst carrier and acetone was used to destabilize the microemulsions to allow the silver particles to stick onto the colloidal silica. The prepared silica-supported Ag catalysts are in a well-dispersed powder state with a color of light yellow. The activity of Ag/ SiO_2 catalysts for the decomposition of H_2O_2 was evaluated in a glass volumetric apparatus and was higher than any catalyst previously tested.

Promoters and Activators for Catalytic Decomposition of Hydrogen Peroxide

It has been claimed that certain organic additives that are compatible with hydrogen peroxide can enhance the startup and the rate of hydrogen peroxide decomposition on silver screen catalysts. Some of the additives said to be active in this regard are organic, unidentified (most likely organic peroxide) contaminants often (unintentionally) remaining in hydrogen peroxide that was made by autoxidation of 2-propanol (i.e., the Shell process). A patent [690] describes a method for decomposing hydrogen peroxide of about 30 to 100 mass-% H_2O_2 , which comprises contacting the hydrogen peroxide with a solid silver-containing decomposition catalyst in the presence of between ~50 and ~10000 mg/L of organic peroxide-containing residue from hydrogen peroxide production by oxidizing an organic compound selected from the group consisting of alkyl anthraquinones, alcohols, hydrocarbons, or hydrazobenzenes.

Along the same line of claims, it has been claimed that addition of 0.7–1.4 mg/L of ions of zinc or cadmium in the form of salts where the anions do not form insoluble salts with silver, for instance, in the form of $\text{Zn}(\text{NO}_3)_2$ or $\text{Cd}(\text{NO}_3)_2$, will improve decomposition of H_2O_2 on fixed bed catalysts and reduce loss of silver catalyst in repeated operation at ambient or lower startup temperatures [691]. It would have generally been predicted that additives for increasing the specific decomposition rate of hydrogen peroxide on solid silver catalysts would be undesirable since they would be expected to make the hydrogen peroxide more unstable during storage prior to use. The additives claimed do not have this disadvantage but are selective in their action. They promote the catalytic decomposition of the hydrogen peroxide by solid silver catalysts but do not increase the rate of hydrogen peroxide decomposition in the absence of such silver catalysts. Similar improvements were said to be achieved by dissolving silver or cadmium salts in the form of their acetate or benzoate salts in amounts that introduce into the hydrogen peroxide about 0.1 to about 10 mg of total zinc and/or cadmium ion per liter of the hydrogen peroxide, most advantageously amounts that provide from about 0.3 to about 3 mg of these metals per liter [692].

4.11 Decomposition of Hydrogen Peroxide by Energetic Radiation

4.11.1 Decomposition of Hydrogen Peroxide by Microwaves

Analysis of the emission spectra from hydrogen peroxide vapor flowing through a low-pressure microwave cavity discharge plasma showed that both $\cdot\text{H}$ and $\cdot\text{OH}$ were produced in proportions that varied with the power applied [693]. When the dissociated vapor was condensed at 195 K, only water was obtained, but at 77 K, H_2O_2 and H_2O_4 were also obtained. Their formation could not be increased by increasing the $\cdot\text{H}$ atom or $\cdot\text{OH}$ radical concentration in the plasma. When the reaction time of the dissociated vapor between the plasma exit, and the cold surface was increased, the rate of H_2O_2 formation increased at the expense of water formation. It appears that, as in the case of the reaction of $\cdot\text{H}$ with O_2 , the rate of H_2O_2 formation is dependent on the concen-

tration of O_2 produced in the spatial afterglow by the gas-phase reactions of the $\cdot OH$ radicals.

In 2003, an SBIR/STTR Phase I contract was awarded to a team from Materials Modification Inc. and Vanderbilt University for the study of microwave-induced thermal decomposition of hydrogen peroxide [694], but there was no follow-on Phase II contract, and there were no publications on the results of this work.

Methods were sought that will heat a small hydrogen peroxide decomposition chamber in a pilot reactor rapidly to a point where catalytic decomposition of hydrogen peroxide can be safely and spontaneously initiated. External heat would have to be applied in the form of an electrically heated heating jacket or a microwave heater to drive off the condensate and facilitate multiple restarts [695]. The heat output from the pilot reactor will then bring the main reactor up to operating temperature. Complex permittivity measurements on hydrogen peroxide with different concentrations were carried out to identify the frequency region for maximum microwave absorption for a given H_2O_2 concentration. Microwave dielectric heating experiments in the frequency region of maximum absorption were then performed to establish a relationship between microwave power requirements and the reactor volume for repeated rapidly heated decomposition of hydrogen peroxide.

4.11.2 Radiolysis of Hydrogen Peroxide

Hydrogen peroxide not only forms in the radiolysis of water, but once formed, it is also decomposed by ionizing radiation. In the end effect, radiolysis of water reaches only a stationary concentration where equal amounts of H_2O_2 are formed and decomposed in a given time period. Hydrogen peroxide that is used as a propellant in satellites is exposed to cosmic radiation that is energetic enough to penetrate the propellant tanks (which is usually made from aluminum, which is a poor radiation shield). The decomposition of H_2O_2 is accelerated by ionizing radiation such as electrons, protons, neutrons, or γ -radiation, most of which are found in cosmic radiation [696, 697]; see also [698].

In an initially oxygen-free neutral H_2O_2 solution, H atoms as well as electrons are formed on irradiation. As the decomposition proceeds, enough oxygen is formed to react with the precursors of the H atoms such that all the reducing species produced are in the form of H_2O^- . It was assumed that the precursors of the H atoms are excited H_2O^* molecules, but such hypotheses were later disputed [699]. Computer calculations of the radiolytic decomposition of dilute hydrogen peroxide solutions have shown that earlier results support the value $ge_{aq} = 2.3$ if the rate constant ratio

$$k(e_{aq^-} + O_2)/k(e_{aq^-} + H_2O_2) = 1.53.$$

Accepting this value of ge_{aq^-} makes the assumption of a small yield of a second oxidizing species unnecessary [700].

Radiolysis of Hydrogen Peroxide by Fast Electrons or Ions

Fast electrons will knock additional electrons out of neutral H_2O_2 molecules and ionize them so that they can be analyzed in a mass spectrometer. The lifetime of H_2O_2^+ is very short, and it will decompose to other species as it travels through the electrostatic and magnetic field of the mass spectrometer or a time-of-flight mass spectrometer.

Mass spectrometric measurements on hydrogen peroxide were carried out with a modulated molecular beam sampling system to eliminate interferences from decomposition products [701]. The mass spectrum of pure hydrogen peroxide differs considerably from previously reported spectra, which did not include an estimate of the H_2O^+ and O_2^+ ion intensities because of decomposition problems. Appearance potentials of the ions were measured with the following results: $I(\text{H}_2\text{O}_2) = 10.92 \pm 0.05 \text{ eV}$, $A(\text{HO}_2^+) = 15.36 \pm 0.05 \text{ eV}$, $A(\text{O}_2^+) = 15.8 \pm 0.5 \text{ eV}$, $A(\text{H}_2\text{O}^+) = 14.09 \pm 0.10 \text{ eV}$, $A(\text{OH}^+) = 15.35 \pm 0.10 \text{ eV}$, and $A(\text{O}^+) = 17.0 \pm 1.0 \text{ eV}$. It was found that the H_2O^+ and OH^+ ions are evolved without excess energy, while the dissociative processes producing O_2^+ and O^+ require excess energy.

Radiolysis of Hydrogen Peroxide by β - or γ -Radiation

Instead of irradiating H_2O_2 externally (and dealing with radiation being absorbed in the glass holding the sample and causing secondary radiation) one can use an internal source of radiation in the form of tritium water T_2O . For irradiation by $\text{T}\beta$ -particles, 6-M H_2O_2 solution was tritiated with T_2O to an activity of 0.3 curie/mL and frozen in glass sample tubes in liquid nitrogen [702]. Tritium was chosen as an internal source of radiation since it allows one to avoid the background of irradiated glass in the EPR spectrum. The resulting EPR spectrum was very similar to the spectra reported for H_2O_2 irradiated by ultraviolet light and has been ascribed to the $\text{HOO}^\bullet$ free radical. It was hoped that one would find H_2O_4 in the condensate.

Radiolysis of H_2O_2 forms $^\bullet\text{HO}_2$ and $^\bullet\text{O}_2^-$ free radicals, which can either recombine or react with more H_2O_2 to sustain a chain reaction. The rates of reaction of $^\bullet\text{HO}_2$ and $^\bullet\text{O}_2^-$ with hydrogen peroxide were studied by ^{60}Co γ -radiolysis as a function of pH at 296.6 K (23.5 °C) [703]. The numerical values for the two rate constants,

$$k(^\bullet\text{HO}_2 + \text{H}_2\text{O}_2) = (0.50 \pm 0.09) \text{ M}^{-1} \text{ s}^{-1}$$

and

$$k(^\bullet\text{O}_2^- + \text{H}_2\text{O}_2) = (0.13 \pm 0.07) \text{ M}^{-1} \text{ s}^{-1}$$

were computed from molecular oxygen yields, which resulted from the radiation-induced chain decomposition of aqueous hydrogen peroxide solutions. The experimental results were consistent with a chain mechanism that takes into account the dissociation of $^\bullet\text{HO}_2$ in equilibrium $^\bullet\text{O}_2^- + \text{H}^+$ ($\text{pK} = 4.7$) and the competition between the reactions ($^\bullet\text{HO}_2 + \text{H}_2\text{O}_2$ and $^\bullet\text{O}_2^- + \text{H}_2\text{O}_2$) and the recombination reactions of the superoxide and perhydroxyl radicals ($^\bullet\text{HO}_2 + ^\bullet\text{HO}_2$ and $^\bullet\text{HO}_2 + ^\bullet\text{O}_2^-$).

A mechanism for the γ -ray initiated decomposition of 0.1-M aqueous solutions of hydrogen peroxide was deduced from data showing a dependence of the decomposition product yield on the square root of hydrogen peroxide concentration and the inverse square root of the dosage rate in intermittent radiation experiments [704]. Termination was shown to occur through a termolecular reaction involving two hydroperoxyl radicals and a hydrogen peroxide molecule. It was shown that

is the rate determining propagation, and

is the chain termination step.

The radiolysis of pure (97%) solid H_2O_2 films by 50 keV H^+ at 17 K was characterized using UV-visible and infrared reflectance spectroscopies, a quartz-crystal microbalance, and a mass spectrometer in order to measure the absolute concentrations of H_2O , O_2 , H_2O_2 , and O_3 products as a function of irradiation fluence [705]. Ozone was identified by both UV and infrared spectroscopies and O_2 from its forbidden transition in the infrared at 1550 cm^{-1} . The radiation yields (G-factors) for the decomposition of hydrogen peroxide were particularly high, which was explained by the participation of chemical chain reactions.

Decomposition of Hydrogen Peroxide by Neutron Radiation

Hydrogen peroxide, or more accurately, deuterium peroxide, forms inadvertently and unavoidably in the heavy water that is used as the moderator and heat transfer fluid in pressurized water reactors of the CANDU type. Deuterium peroxide that has formed in this way will be decomposed just as fast by neutron radiation, thus a stationary concentration will be achieved in a closed-loop system. Sampling the coolant loop water will show low D_2O_2 concentrations because thermal decomposition continues even after the coolant leaves the hot zone of the reactor.

As a model for D_2O_2 reactions in heavy-water moderated nuclear reactors, the thermal decomposition rate of H_2O_2 was measured in the aqueous phase at elevated temperature [706]. It was shown that the reaction follows first-order kinetics, and the rate constant was determined as a function of temperature. A mechanism was derived for the aqueous phase decomposition in relation to the activation energy of the reaction. Calculations were carried out for the reactions of O_2 , H_2 , and H_2O_2 in the boiling water reactor sampling line. It was shown that some H_2O_2 (and D_2O_2) disappears before the analysis can be completed.

Radiolysis of Hydrogen Peroxide by X-Rays

X-ray irradiation not only initiates the formation of hydrogen peroxide from water but also causes the decomposition of hydrogen peroxide once it is formed [707]. In an ap-

paratus with continuous X-ray irradiation of water, only a small stationary concentration of H_2O_2 is attained (at the best).

4.11.3 Photolysis of Hydrogen Peroxide

Photolysis of hydrogen peroxide is discussed here in quite some detail because photolysis affects the use of hydrogen peroxide as a rocket propellant and many other applications. Photochemical processes lead to the formation and decomposition of hydrogen peroxide in many locations, not only on Earth but also on other celestial bodies, and possibly even in interstellar space.

It is certain that large quantities of hydrogen peroxide are formed on the icy moons of the large planets Jupiter and Saturn under the influence of UV radiation from the sun. At the same time, hydrogen peroxide that has collected in the ice will be destroyed by the same radiation that helped its formation in the first place. There are tons of hydrogen peroxide floating around in the atmosphere and stratosphere on Earth, and it is subject to photolysis just as fast as it forms under the influence of UV radiation. If one conducts H_2O_2 photolysis studies with gradually shorter and shorter wavelength light, the wavelength of light where H_2O_2 is first observed to decompose is an indication of the bond energies and the level of excitation (vibration and rotation) that ultimately leads to dissociation of the molecule. This level can be measured experimentally and predicted by quantum mechanical calculations. This section deals with both methods.

Photolysis interferes with analytical spectroscopic methods, where the initial intent was to measure the absorption of light, but the light caused the premature decomposition of the analyte at the same time.

Photolysis, often in combination with catalysts, would be the preferred and environmentally friendly method for destruction of hydrogen peroxide in wastewater, rinse waters from propellant spills, and disposal of surplus hydrogen peroxide (after sufficient dilution with water).

Laser photolysis has been considered as a method to initiate decomposition of hydrogen peroxide (and other monopropellants) in thrusters, thus becoming independent of the limited lifetime of catalysts often used for the initiation of hydrogen peroxide decomposition in thrusters. Photolysis of H_2O_2 by intense laser light would be a reliable method to initiate the decomposition of HTP in a rocket engine, even with multiple starts and pulse-mode operation.

Hydrogen peroxide is a reactant in chemical lasers, and its premature photolysis would interfere with the operation of the laser.

Photolysis mechanisms of the decomposition of hydrogen peroxide are very similar to the mechanisms during radiolysis by other types of energetic radiation. The two chapters are closely related and complement each other. Radiolysis of rocket propellants stored in space and subjected to cosmic radiation is inevitable.

Photolysis of hydrogen peroxide with quenching of the reacting mixture may be a method to synthesize superoxides of hydrogen, such as $\text{H}-\text{O}-\text{O}-\text{O}-\text{O}-\text{H}$, which should make good rocket propellants (if they are stable at room temperature).

Photolysis of hydrogen peroxide is a convenient and clean method for generating a stream of hydroxyl-free radicals, which are often used to study reactions with other materials, including living cells, where they can cause mutations. The photolysis of 1-M hydrogen peroxide can effectively kill oral pathogenic microorganisms.

Photolysis experiments with H_2O_2 can be conducted with the chemical in the vapor, solid, or liquid state. Most of the experiments were conducted with H_2O_2 vapor, which is the state it is encountered in the Earth atmosphere. However, additional photolysis experiments were conducted with frozen H_2O_2 or H_2O_2 in a matrix of water ice, simulating the condition in which it may occur in other parts of the solar system. Photolysis of frozen H_2O_2 in a matrix of frozen noble gases allows one to trap some of the short-lived free radicals that play a key role in H_2O_2 formation and photolysis.

Photolysis of Hydrogen Peroxide Solutions

The quantum yield of the photochemical decomposition of hydrogen peroxide at relatively high light intensity is independent of the concentration of hydrogen peroxide, of acidity, and of the presence in the solution of Br^- , Cl^- , NH_4^+ , or Mn^{2+} [708]. At 298 K (25 °C) the limiting quantum yield at 2537 Å is 0.98 ± 0.05 and at 273 K (0 °C) it is 0.76 ± 0.05 . The primary efficiencies were taken as 1/2 of the limiting quantum yields. Tracer experiments showed that the oxygen formed in the photodecomposition originated entirely from the hydrogen peroxide. The exchange between O_2 and H_2O_2 during the photodecomposition is at most very slight.

In aqueous hydrogen peroxide-formic acid solutions, a chain reaction is initiated by ionizing radiation or by 2537 Å light absorbed by the hydrogen peroxide. The principal gaseous product is carbon dioxide. The reaction is inhibited by oxygen, and from the quantum yield of oxygen consumption the primary quantum yield of hydrogen peroxide dissociation at 2537 Å was deduced to be 0.49 ± 0.065 [709]. From this yield and a comparison of the photochemical experiments with those in which the reaction is induced by γ -rays, one can calculate a G value of 3.06 water molecules decomposed to radicals per 100 eV of absorbed energy. These results suggested that the higher primary quantum yield reported earlier was in error. An alternate mechanism was proposed that fits the experimental data better.

Photolysis of Hydrogen Peroxide Vapor

The dynamics of photodissociation of H_2O_2 from low-lying excited electronic states was studied by classical trajectory calculations [710]. Potential energy functions were constructed for both the ground state and two excited states of H_2O_2 . Parameters in the ground-state function were chosen to fit measured vibrational frequencies, potential barriers, and the equilibrium structure. Parameters in the excited state functions were chosen to fit the observed $\bullet\text{OH}$ rotational state distribution and to be consistent

with the electronic spectrum. The moderate rotational excitation of the $\bullet\text{OH}$ radicals is mostly explained by the fact that the repulsive O—O force exerts a small torque around the center of mass of the $\bullet\text{OH}$ radicals as they leave the molecule.

A complete characterization of the scalar and vectorial properties of the $\bullet\text{OH}$ fragment formed by photodissociation of jet cooled H_2O_2 using Doppler and polarization spectroscopy showed that when hydrogen peroxide is optically excited at 193 nm, the hydroxyl radicals are formed exclusively in the $X^2\Pi_{3/2,1/2}$ ground state with 84% of the available energy ($E_{\text{av}} = 417 \text{ kJ/mol}$) being released as OH recoil translation [711, 712]. The remaining energy is transferred in product rotation. Vibrationally mediated photodissociation of hydrogen peroxide and variable curvature coordinates for molecular vibrations were described in [713].

In order to elucidate the mechanism of H_2O_2 photodissociation, especially the origin of the Λ -type preference of product $\bullet\text{OH}$, the potential energy surfaces containing the singlet and triplet states were calculated and the spin-orbit coupling was examined [714]. The relation of the Λ -component ratio with the product rotation J was consistent with the experimental findings of vector correlation.

A reinvestigation of the vibrationally mediated photodissociation spectrum of the third OH stretching overtone ($4\nu\text{OH}$) of jet-cooled H_2O_2 revealed anomalous double resonance spectral intensities compared with those observed via high-resolution absorption spectroscopy [715]. The origin of these intensity perturbations is traced to $J'\text{KaKc}$ level-dependent variations in the photodissociation cross section, δ_{00} , out of the intermediate overtone state. The photofragment $\bullet\text{OH}$ ($X, v = 0$) rotational state distribution generated by photodissociation of H_2O_2 ($4\nu\text{OH}$, $J'\text{KaKc} = 202$) was then determined. Combined with the relative cross-section data, these results implied that delocalization of the overtone state wavefunction into wide amplitude O—O stretching regions of the ground state is profoundly influenced by parent molecular rotation, primarily about the a and b axes. The intermediate state with $J' = 0$ was shown to be much more highly localized, and hence more likely to display mode selective behavior, than its $J' > 0$ counterparts.

The near-threshold dissociation of overtone-induced H_2O_2 corresponds to the dissociation through combination modes that contain five quanta in the OH local-mode stretching vibration, and various amounts of energy in other modes, such as O—O stretching, OOH bending, torsion, and molecular rotation [716]. The lifetime depends on whether or not the O—O stretching mode contains any excitation. The lifetimes of the bending combination modes are strongly affected by torsion and/or rotation, whereas the O—O combination lifetimes are less influenced by such additional excitations.

The primary quantum yields of $\bullet\text{OH}(X^2\Pi)$, $\text{H}(^2\text{S})$, and O atoms [$\text{O}(^1\text{D}) + \text{O}(^3\text{P})$] produced in the photodissociation of H_2O_2 at 193 and 222 nm were measured at 298 K [717]. At 193 nm, the primary quantum yields were 1.51 ± 0.18 , 0.16 ± 0.04 , and <0.02 , for $\Phi(\text{OH})$, $\Phi(\text{H})$, and the sum of $\Phi(\text{O})$ and $\Phi(\text{O}(^1\text{S}))$, respectively. At 222 nm, the OH yield was $\Phi(\text{OH}) = 2.02 \pm 0.35$, the H atom yield was $\Phi(\text{H}) = 0.024 \pm 0.012$, and $\Phi(\text{O})$ was

<0.002 . The OH product was directly monitored by pulsed laser-induced fluorescence, and the atomic species were detected via continuous wave (CW) resonance fluorescence. The OH quantum yields reported were measured relative to known product quantum yields in the dissociation of H_2O_2 at 248 nm. Up to 15% of the OH produced in the 193 nm photolysis may be vibrationally excited, but no evidence of vibrationally excited OH was observed at 222 nm.

Quantum mechanical calculations were carried out for UV photodissociation of H_2O_2 at photon energies of 248 nm [718]. The photodissociation process of H_2O_2 was simulated by the standard two-surface energy surface model using an *ab-initio* ground potential energy surface and a simple empirical excited surface. A time-dependent approach was employed in quantum dynamics calculations due to the short lifetime transient nature of the dissociation process. The computed rotational state distribution of the OH fragments was in qualitative agreement with results published by earlier investigators, with most of the excess energy being carried away by the relative translational motion of the $\bullet\text{OH}$ fragments. The effect of torsional mode on the rotational state distribution was investigated by calculating the Franck-Condon factors of photodissociation using torsionally excited bound state wavefunctions.

A quantum mechanical study on UV photodissociation of H_2O_2 at 248 and 266 nm looked at the rotational distributions of the product $\bullet\text{OH}$ on both the A and B energy surfaces [719]. The $\bullet\text{OH}$ radicals were found to be considerably hotter than those obtained in a previous quantum mechanical calculation. The dissociation preferentially produces $\bullet\text{OH}$ rotations with a high $J_1 \sim J_2$ correlation. These conclusions were in good agreement with earlier calculations.

Hydrogen peroxide was photodissociated at 355 nm using both linearly and circularly polarized light, and $\text{OH}(^2\Pi)$ rotational distributions, spin-orbit branching ratios, doublet populations, and angular momentum J polarization were measured by polarized laser probing of the products using laser induced fluorescence [720]. There was evidence supporting preferential dissociation of ground-state molecules far from the equilibrium configuration, indicating possible mechanisms for the orientation of the product's angular momentum in the molecule frame.

The photolysis of hydrogen peroxide is a free radical reaction. The rate of decomposition of hydrogen peroxide vapor by photolysis at very low pressures, simulating processes in the upper atmosphere, will be affected by addition of free radical scavengers or reducing agents like hydrazine or hydroxylamine [721, 722]. The quantum yield of H_2O_2 photolysis decreased by 50% in the presence of hydrazine. It is known that the combination of hydrogen peroxide and hydrazine in the liquid state or at higher vapor concentrations is hypergolic, so one is curious why anyone would want to study the reaction of the two rocket propellants at very low pressures with illumination by actinic light. At higher concentrations, ultraviolet light illumination would trigger ignition of the two chemicals; see also [379].

4.11.3.1 Photolysis of Frozen Hydrogen Peroxide

Hydroxyl radicals formed by UV photolysis of hydrogen peroxide-water solutions can be trapped in a matrix of frozen ice at 90 K and identified by analysis with an electron spin resonance spectrometer [723, 724].

Fourier transform IR and luminescence spectroscopy diagnostics applied to UV-induced (from 193 to 380 nm) photolysis of H_2O_2 in solid argon at 18 K showed that the major photolysis products were: **(1)** a complex of monomeric water with atomic oxygen and **(2)** free $\cdot\text{OH}$ radicals [725]. A three-component photokinetic scheme

described all the features observed quite well. The wavelength dependence of the kinetics was measured, which gave the rate constants as a function of excitation wavelength. It was proposed that a photoinduced charge transfer between H_2O and O takes place with concomitant recombination into H_2O_2 .

Similar photorecovery of H_2O_2 from the tight $\text{H}_2\text{O}\cdots\text{O}$ complex was observed in Kr and Xe matrices instead of an Ar matrix [726]. The similarity of spectral position and efficiency of the photorecovery reaction in various rare gas solids indicated its fundamental character, supporting the theory of charge-transfer excitation of $\text{H}_2\text{O}\cdots\text{O}$ as its origin. In UV photolysis of H_2O_2 , a relatively small concentration of isolated $\cdot\text{OH}$ radicals was found in a Kr matrix, and no $\cdot\text{OH}$ radicals appeared in a Xe matrix. Among the photolysis products, the loose $\text{H}_2\text{O}\cdots\text{O}$ complex may be stabilized in Kr and Xe matrices. This loosely bound complex is quasistable and decomposes at relatively low temperatures (<20 K), quantitatively forming the known tight $\text{H}_2\text{O}\cdots\text{O}$ structure.

4.11.4 Decomposition of Hydrogen Peroxide in Intense Ultrasound Fields

It has been proposed to achieve instant decomposition of HTP by first aerating it with many small bubbles of an inert gas with a high adiabatic coefficient (e.g., helium with $\gamma = 1.66$) and then passing it through an intense ultrasonic (20 kHz) field [727]. Ultrasonic agitation and cavitation cause a dissipation of kinetic energy per unit mass of the fluid. This dissipation of turbulent energy will provide enough heat to instantly initiate decomposition of hydrogen peroxide, e.g., in a rocket engine.

4.12 Decomposition of Hydrogen Peroxide in the Vapor Phase

Hydrogen peroxide vapor decomposes much faster than H_2O_2 in the liquid phase, in particular at temperatures near or even above its sea-level pressure boiling point. The rate of hydrogen peroxide vapor decomposition depends on the vapor concentrations, temperature, pressure, vessel size, and mode and level of initiation stimulus. Both homogeneous and heterogeneous decomposition take place in a competing fashion.

The heterogeneous rate is very dependent on the wall material that the vapor is in contact with.

The slow vapor phase decomposition of hydrogen peroxide can be investigated in closed vessel static reactors (with manometric or spectrometric tracking of the progress of the reaction) or in dynamic flow reactors with on-line analyzers (such as mass spectrometers or spectrophotometers), or grab samples taken at specific times. The fast decomposition can be analyzed in shock tubes (usually with fast-registering spectroscopic diagnostics of the reacting species).

Satterfield and coworkers [728, 729] conducted a thorough study of hydrogen peroxide vapor decomposition and concluded that in the end all surfaces, also extremely clean ones, accelerate the decomposition of H_2O_2 vapors. Parts of the studies were conducted in a tubular reactor [730], while the rest of the experiments used a packed bed reactor with a larger exposed surface area [731]. Quartz and borosilicate (Pyrex[®]) glass are not as active as soft glass or even metal surfaces. Homogeneous decomposition was insignificant under all conditions studied there; it does not become appreciable at these concentrations until temperatures of about 723 K (450 °C) are reached. The experimental apparatus consisted of a vaporization section and a decomposition section. In the vaporization section, a hydrogen peroxide-water solution was fed continuously to an electrically heated borosilicate glass boiler through a leveling device that maintained a constant liquid level in the boiler. The boiler pressure was regulated by an external helium system. This system was capable of producing a steady flow of hydrogen peroxide vapor at a constant concentration. The hydrogen peroxide-water vapor mixture from the boiler first passed through an entrainment separator (aerosol trap) and then through an electrically heated borosilicate glass preheater. A portion of the vapor at this point was withdrawn for analysis by condensing it in a cold trap and determining the hydrogen peroxide content by potassium permanganate titration. The remainder of the vapor flowed through the reaction tube, and the effluent from the reactor was similarly condensed and analyzed. In passing the $\text{H}_2\text{O}/\text{H}_2\text{O}_2$ vapor over a non-porous catalyst in a tubular reactor, the H_2O_2 concentration was varied from 3 to 32 mass-%, the catalyst temperature was varied from 478 to 755 K (400 to 1000 °F), and the Reynolds number in a 6.3 mm diameter and 46 or 61 cm long bed was varied from 3200 to 10000. In tests with a packed bed of 5-mm diameter silver beads in a 4.8-cm or 7.5-cm diameter reactor, with a catalyst bed length of 2.4 cm, the H_2O_2 concentration was varied from 5 to 24 mass-%, the catalyst temperature was varied from 478 to 811 K (400 to 900 °F), and the Reynolds number in a 4.8 cm diameter reactor was varied from 22 to 161.

4.12.1 Kinetics of Slow H_2O_2 Decomposition in the Vapor Phase

A thorough understanding of the kinetics of H_2O_2 decomposition in the vapor phase will help the rocket engineer avoid hazardous conditions in the vapor space above liquid H_2O_2 in missile and satellite tanks, and in the coolant jacket and injector of rocket

engines, where H_2O_2 may evaporate after engine shutdown. The kinetics of H_2O_2 vapor decomposition also influence the efficiency of heterogeneous catalysts in H_2O_2 -powered gas (steam) generators and rocket engines. Decomposition of H_2O_2 vapor can proceed by several pathways, but the main end products are always water (steam) and oxygen.

The O—O bond is the weakest bond in the molecule and as such the most likely one to rupture first. Intermediate reactions in the thermal decomposition of hydrogen peroxide are likely those involving dissociation into two hydroxyl-free radicals as the first step:

Subsequent disproportionation of hydroxyl radicals or hydrogen abstraction leads to the ultimate decomposition products.

Decomposition of energetic chemicals starts with breaking a chemical bond. Before starting to summarize the H_2O_2 decomposition kinetics literature, one can categorize the various reactions by the type of initial valence bond breaking process. Five types of initiation can readily be recognized. The vertical arrow indicates the place of bond scission:

The top two reactions do not involve electrically charged (ionic) fragments. The first two methods of bond breaking are examples of homolytic valence bond fission. Each fragment carries a free electron, which is characteristic of a free radical. The radicals formed are hydroxyl radicals $\text{HO}^\bullet$ in the first case (a hydroxyl radical mechanism), and hydroperoxyl (“perhydroxyl”) $\text{HOO}^\bullet$ and atomic hydrogen $\text{H}^\bullet$ in the second case.

The dot indicates the free electron. The lifetime of hydroxyl radicals in the presence of water vapor or in aqueous solutions can be extended by a rapidly occurring proton exchange.

The last three heterolytic scission mechanisms in which the electron from the shared bond remains with one of the fragments result in electrically charged ions. Therefore, these types of mechanisms are called ionic mechanisms. Mechanism (3) is called a hydroxyl ion mechanism. The last mechanism, mechanism (5) leading to a hydride ion H^- is very unlikely to occur and can be neglected in the following discussion.

The remaining four mechanisms can occur side-by-side as competing mechanisms. In most cases it is possible to identify the prevailing mechanism or the rate-determining mechanism. In the vapor phase with thermal, photolytic, glow discharge, or radiolytic stimulation, a free radical mechanism is most likely, not only for plain decomposition of pure H_2O_2 , but also for its reaction with other species. In the liquid phase, in aqueous solutions, it is more likely to encounter ionic species as intermediates, depending on the pH of the solution.

The reaction mechanisms of H_2O_2 decomposition have been elucidated by isotope labeling of either the hydrogen (deuterium or even tritium) or the oxygen (^{18}O) positions.

When the first shipments of impounded German HTP reached the shores of the US after WW-II, very little was known about the decomposition kinetics of this chemical. Consequently, largely with US Government funding and in support of on-going efforts to use HTP as an energy source and rocket propellant, H_2O_2 decomposition kinetics under various conditions (liquid and vapor) and with and without the presence of catalytic surfaces was actively investigated, resulting in a flood of reports and publications during the years 1945 through 1959.

The kinetics of the decomposition of hydrogen peroxide in the vapor state were studied by a static manometric method at pressures ranging from 10 to 20 mm Hg and temperatures from 343 to 473 K (70 to 200 °C), starting with pure hydrogen peroxide at a concentration of about 99.5 mass-% H_2O_2 and using Pyrex[®] or soda-glass vessels [732]. Under these conditions, the reaction was purely heterogeneous, of the first order up to 413 K (140 °C) but more complicated at higher temperatures. The rates were not affected by air, carbon dioxide, or water vapor, but they varied greatly with the size and shape of the vessel. The reaction was very slow on fused Pyrex[®] but very rapid on soda-glass. No explosions were encountered up to 608 K (335 °C) at a pressure of 180 mm Hg. The apparent activation energies in various vessels ranged from 56.4 to 77.4 kJ/mol (13.5 to 18.5 kcal/mol), which is much lower than that of a true vapor decomposition reaction.

The decomposition of hydrogen peroxide vapor at pressures of less than 1 mm Hg in silica vessels has been investigated over the temperature range 288–413 K (15–140 °C) with most data taken at 353 K (80 °C) [733]. Oxygen at low pressures was

found to have no appreciable influence on the rate of decomposition, but water vapor retarded the rate slightly. The reaction was predominantly a surface catalyzed reaction. In one vessel, the decomposition was bimolecular with respect to the peroxide pressure, the rate being given by

$$k[\text{H}_2\text{O}_2]^2/(1 + b[\text{H}_2\text{O}])^2.$$

In another case, the bimolecular reaction of the final stages at low peroxide pressures was preceded by one of order approximately 0.7 at the higher pressures. Higher pressures of oxygen and nitrogen retarded the decomposition appreciably. At higher pressures of water vapor, a pronounced periodicity in rate was evident. The apparent activation energy over the temperature range investigated was not constant. It was 4.2 kcal/mol from rates at 288–413 K (15–70 °C) and 8.4 kcal/mol from rates at 353 and 413 K (80 and 140 °C). On the assumption that the lower value more closely represents a surface reaction, the velocity of decomposition, calculated for 1 mm Hg pressure of peroxide at 323 K (50 °C) by the theory of absolute reaction rates, was $0.70 \times 10^{13} \text{ mol cm}^{-2} \text{ s}^{-1}$, in agreement with the experimental value of $0.76 \times 10^{13} \text{ mol cm}^{-2} \text{ s}^{-1}$.

Decomposition of H_2O_2 vapor can proceed by several pathways; the main products are always water (steam) and oxygen. The following reactions are possible in H_2O_2 decomposition, but not all participate to the same extent. The reaction energies at 298 K of several of these reactions are summarized in Table 47.

Table 47: Reaction energy of hydrogen peroxide decomposition reactions.

Reaction	Enthalpy, kcal/mol	Enthalpy, kJ/mol
$\text{O}_2 \rightarrow 2\text{O}$	118.3	495
$\text{H}_2\text{O} \rightarrow 2\text{H} + \text{O}$	221.1	925
$\text{H}_2\text{O} \rightarrow \text{H} + \text{OH}$	119.9	502
$\text{OH} \rightarrow \text{O} + \text{H}$	101.2	423
$\text{H}_2\text{O}_2 \rightarrow 2\text{H} + 2\text{O}$	254.9	1067
$\text{H}_2\text{O}_2 \rightarrow 2\text{OH}$	52.6	220
$\text{H}_2\text{O}_2 \rightarrow 2\text{H} + \text{O}_2$	136.6	572
$\text{H}_2\text{O}_2 \rightarrow \text{H} + \text{O}_2\text{H}$	90	377
$\text{O}_2\text{H} \rightarrow \text{H} + \text{O}_2$	46 (uncertain)	192 (uncertain)

In this table, the dissociation of H_2O_2 into two hydroxyl-free radicals has one of the lowest energy levels and is most likely the easiest one to achieve with only modest levels of energy input as a stimulus. Intermediate reactions in the thermal decomposition of hydrogen peroxide are likely those involving the first step of dissociation into two hydroxyl-free radicals:

The O—O bond is the weakest bond in the molecule, and as such the most likely one to rupture first. Subsequent disproportionation of hydroxyl radicals or hydrogen abstraction leads to the ultimate decomposition products.

The decomposition of hydrogen peroxide at partial pressures of 1–2 mm Hg was studied in the presence of one atmosphere of oxygen or nitrogen or hydrogen using a flow system [734, 735]. The concentration of H_2O_2 was measured photometrically, using continuous ultraviolet absorption. Measurement by this means was more rapid and allowed less chance of errors of manipulation than wet chemical analysis. A first-order reaction with an activation energy of 40 kcal/mol was found for the homogeneous reaction in boric acid treated vessels at temperatures in the 470 to 540 °C range. Data in the presence of hydrogen indicated that the reaction proceeds by a chain mechanism involving no direct reaction between hydrogen and hydrogen peroxide molecules, at least not at low hydrogen concentrations. It was found that hydrogen+oxygen mixtures undergo appreciable reaction at temperatures where the rate of reaction is normally very small if small amounts of hydrogen peroxide are added first.

Another possible pathway involves the dissociation into hydroperoxyl free radicals and atomic hydrogen [736]:

Other decomposition pathways involve ionic species. One mode of dissociation is

This reaction also occurs in the liquid phase and is responsible for the weakly acidic reaction of H_2O_2 solutions. At 298 K, the equilibrium constant for this reaction is 2.24×10^{-12} .

The thermal decomposition of hydrogen peroxide vapor was investigated by a static method as a function of initial pressure at pressures up to 22 mm Hg, and in the presence of inert gas (helium, oxygen, and water) up to 100 mm Hg [737]. In each case, the apparent first-order rate constant increased linearly with pressure. It was demonstrated that under those experimental conditions, the pyrolysis of hydrogen peroxide showed behavior typical of an elementary unimolecular reaction in its low-pressure, second-order region. The reaction was accompanied by a heterogeneous decomposition, which in the presence of foreign gas became inhibited. Helium was used as inhibitor over the temperature range 703–743 K (430–470 °C), which permitted calculating the activation energy for activation with peroxide and with helium. The kinetic rate expression is $10^{15.7} \exp(-48000/RT) \text{ L mol}^{-1} \text{ s}^{-1}$. It was noted that the preexponential term is much higher than the normal collision rate, which is why others postulated a chain reaction.

A flow system was used to investigate the decomposition of hydrogen peroxide vapor between 514 and 932 K (241 and 659 °C) [738]. It was shown that above 693 K

(420 °C), a homogeneous decomposition predominates, which is second order and occurs by the reactions:

followed by

The first reaction, which is rate-determining, occurs at a velocity depending upon the efficiency of M; the experimental order of third-body efficiencies being $\text{H}_2\text{O}_2 > \text{H}_2\text{O} > \text{CO}_2 > \text{N}_2 > \text{O}_2 > \text{He}$. When hydrogen peroxide was taken as M (the absence of diluent gases), the rate constant of the first reaction was calculated to be $10^{15.4} \exp(-48000/RT) \text{ L mol}^{-1} \text{ s}^{-1}$. It was shown that the results of earlier research were consistent with the above reaction scheme and rate constant. Although there have been several investigations into the kinetics of the decomposition of hydrogen peroxide vapor, there was no general agreement with respect to the order of the reaction or the magnitude of the activation energy of the vapor phase decomposition in the absence of catalytic surfaces [739]. In order to determine this, one of the main experimental difficulties was the elimination of heterogeneous decomposition. Some investigators used reaction vessels coated with boric acid, while others found that this coating was unsatisfactory and recommended the use of clean Vycor glass. Others used phosphoric acid coated vessels. Eventually, it was decided to use clean Pyrex[®] and silica vessels, which had been cleaned by rinsing with 40% hydrofluoric acid. It was shown that Pyrex[®] and silica surfaces thus cleaned are effective in the preservation of liquid and gaseous hydrogen peroxide. One series of experiments employed a flow reactor from Pyrex[®] (38 mm I.D. and 20 cm L) and an inert gas at 1 atm pressure as carrier, the hydrogen peroxide being decomposed at 241 to 478 °C. The source of vapor was from 85% hydrogen peroxide (containing a non-volatile stabilizer) kept in two or three bubblers whose temperatures could be adjusted.

Earlier investigators found the order of the homogeneous gas-phase decomposition of hydrogen peroxide to be unity with respect to peroxide. They also found the rate to be independent of total pressure. Forst [737] and Hoare, Protheroe, and Walsh [738] established both the first-order nature of the decomposition and the dependence of the rate on total pressure. This was confirmed and the range of experimental investigations was extended, and the decomposition of H_2O_2 in the presence of H_2 was examined [740]. For this study, the carrier gas (normally N_2) was saturated at 293 K (20 °C) by passage through two bubblers in series containing 90 or 99% H_2O_2 . A second diluent stream of N_2 could be added after the saturators. A large bulb ensured complete mixing, and in experiments with H_2 a third stream containing H_2 could also be added. The gas was then split into two almost equal parts by two capillary tubes in parallel. One stream passed directly through two cold traps in series, which condensed the perox-

ide vapor at 193 K (−80 °C). The second stream passed through the hot reaction vessel and then through cooled traps. The system could be operated at pressures down to 25 mm Hg. Reaction vessels were 20 cm in length, of diameters 6, 12, and 24 mm, with inlet and exit tubes of 6 mm bore. Plotting the data of homogeneous decomposition of H_2O_2 in aged boric-acid-coated vessels for three different diameters (23, 12, and 6 mm) and two different temperatures (762 K = 489 °C and 732 K = 459 °C) showed that the homogeneous process for the three vessel diameters was independent of diameter. The previously assumed activation energy $E = 190.3 \pm 2.1 \text{ kJ/mol}$ ($45.5 \pm 0.5 \text{ kcal/mol}$) agreed well with the value of $k_7 = 8.5 \times 10^{13} \exp(-45500/RT) \text{ mol L}^{-1} \text{ s}^{-1}$ obtained from the slope of that curve. With pure H_2 as carrier gas, the half-life relation suggested an order of approximately 1.5. Plotting the variation of the initial decomposition rate with the mol fraction x of H_2 for two initial concentrations of H_2O_2 showed that the initial rate increased linearly with x initially, then a maximum was reached, and the rate then decreased as x was further increased.

Hydrogen peroxide is an intermediate in the oxygen/hydrogen combustion reaction, but it decomposes just as fast as it forms [117]. The role of hydrogen peroxide in the formation of singlet atomic oxygen in the COIL chemical laser has been extensively investigated. The question has arisen why atomic singlet Δ oxygen cannot be generated from hydrogen peroxide directly without the involvement of chlorine or hypochlorite. A study of hydrogen peroxide decomposition kinetics with regard to hydroxyl-free radical formation and singlet oxygen formation was done in the hope of explaining the interaction of reacting hydrogen peroxide on the surface of hybrid fuels [741]. It was tried to demonstrate, from thermodynamic and kinetic point of views, the effect of introducing singlet oxygen and hydroxyl radicals into the gaseous mixture that can oxidize the solid fuel in a hybrid engine. From a literature survey, it has been shown that both reactants can be formed by the decomposition of hydrogen peroxide on selective catalysts, but under conditions quite different from the real-world operating conditions in a rocket engine. This paper contains a set of kinetic rate data that are also useful for kinetic evaluation of other reactions involving H_2O_2 .

4.12.2 Slow Vapor Phase Decomposition of Hydrogen Peroxide

It is difficult to study the vapor phase decomposition of pure hydrogen peroxide without interference from the wall materials. Most wall materials, even if they have previously been passivated, exert a catalytic effect on the decomposition reaction, which makes it difficult to determine kinetic rates of the homogeneous vapor reaction. Often, tests are conducted with different volume : surface ratios in order to single out surface effects. All these vapor phase decomposition tests were conducted at very low pressures. There are hardly any vapor phase decomposition tests that were conducted at rocket engine operating pressures, which is what we really need to know. Everything else is just an academic exercise that may be of interest to atmospheric pollution meteorologists but not to rocket propellant chemists.

4.12.2.1 Closed Vessel Static Reactor Experiments

The decomposition of H_2O_2 vapor was studied at low pressures in the temperature range from 323 to 693 K (50 to 420 °C) to determine the effect of the type and the pretreatment of the surface of the reaction vessel [742]. One-liter round bottom flasks made of Pyrex[®], soft glass, quartz, or metalized glass were used as reaction vessels. In most cases, the decomposition was found to be of the first order, but the rates varied from one vessel to another, even those made of the same type of glass. In a quartz vessel, the reaction at low temperatures was preceded by an induction period. The marked surface effects pointed strongly to a heterogeneous reaction, which was further shown by a wide spread of values for the energy of activation from 8 to 20 kcal/mol. The catalytic nature of the decomposition due to wall effects is difficult to characterize.

The kinetics of the vapor-phase decomposition of H_2O_2 were studied by a static method at 0.2–20 mm Hg between 573 and 873 K (300 and 600 °C) [743]. The rates were first order with respect to time, and the reaction products were H_2O and O_2 . Below 673 K (400 °C) the surface-catalyzed reaction predominated, whereas above 673 K the gas phase reaction was faster. After correction for the residual surface decomposition, the vapor rate equation becomes

$$k = 10^{13} \exp(-48000/RT) \text{ s}^{-1}$$

With initial pressures around 1.3 kPa (10 mm Hg), the apparent activation energy was 180 kJ/mol = 43 kcal/mol. On subtracting the extrapolated rate of surface decomposition from the overall rate, the activation energy for the homogeneous reaction was estimated to be 201 kJ/mol (48 kcal/mol), or about the magnitude of the O—O bond dissociation energy. The rate increased with increasing partial pressure. The presence of inert gases or glass packing had only a slight effect. D_2O_2 vapor showed the same rate as H_2O_2 vapor. The following mechanism was suggested:

This is rate determining and is followed by:

4.12.2.2 Dynamic Flow Reactor Experiments

It is very difficult to eliminate wall effects if one wants to measure homogeneous vapor decomposition of hydrogen peroxide. A study of the thermal decomposition of hydrogen peroxide vapor under flow conditions in a relatively inert glass reactor showed a transition from heterogeneous to homogeneous reaction in the temperature range of 673 to 723 K (400 to 450 °C), at a partial pressure of 2 kPa (0.02 atm) [744]. The homogeneous reaction was at 3/2 order and had an activation energy of 230 kJ/mol

(55 kcal/mol). The decomposition mechanism appears to involve a very long straight chain reaction.

A series of US Government contracts in the late 1940s and throughout the 1950s sustained a very active research group at Massachusetts Institute of Technology in Cambridge, MA, which resulted in many progress reports, several Master's and PhD theses, and a book on the decomposition of hydrogen peroxide [745–748].

The heterogeneous decomposition of H_2O_2 vapor on platinum or CRES-304 was studied in a 6-mm (0.25 in.) ID tubular reactor at temperatures of 403 to 733 K (130 to 460 °C), Reynolds numbers of 370 to 4100, and vapor concentrations up to 2.1 mol-% H_2O_2 at atmospheric pressure [729, 749]. Nitrogen carrier gas was passed through HTP in a bubbler flask in a constant temperature bath and saturated with H_2O_2 according to its vapor pressure at that preselected temperature. The reactor(s) had an ID of 6 mm and were 91 cm (36 in.) long and carried an array of thermocouples. The platinum reactor was a copper tube with a 0.47 mm (0.0185 in.) thick platinum coating on its inside. All data showed first-order overall kinetics with respect to H_2O_2 , which were not affected by the presence of O_2 , H_2O or N_2 . A surprising result was that the first-order overall rate constant for H_2O_2 decomposition on platinum or stainless steel went through a maximum at about 573 K (300 °C). For a fixed Reynolds number in either the laminar or turbulent flow region, the overall rate constant went through a maximum. The slope of the Arrhenius plot of the log of the rate versus the reciprocal absolute temperature on CRES 304 indicated an activation energy of 60 kJ/mol (14.3 kcal/mol). Another Arrhenius plot provided a comparison of the silver and stainless steel data from this study to data reported for the homogeneous decomposition and decomposition on Pyrex[®] glass cleaned with either phosphoric acid or hydrofluoric acid.

A special type of flow reactor consisting of a tube whose walls are made of a porous material through which an inert gas can be passed to reduce diffusion of the reacting species back to the potentially catalytic vessel surface was used for the study of homogeneous H_2O_2 vapor decomposition [750]. This method allows one to separate the relative contributions of homogeneous and surface-catalyzed effects in a gaseous reaction involving both mechanisms, or at least to minimize the surface effects. Porous-walled tubes of Pyrex[®] (fritted glass) or CRES-316 were jacketed, respectively, with impervious Pyrex[®] or CRES tubes, wrapped with a heating jacket and mounted vertically. Flow rates through the core tube were 0.04 to 0.4 mol H_2O_2 /min, and reactor temperatures were from 358 to 451 K (85 to 178 °C). The inert carrier gas was bubbled through thermostatted HTP solutions and picked up ~4 mol-% H_2O_2 , along with some water. Diluent gas flowing through the porous wall prevented H_2O_2 from contacting the hot wall.

4.12.2.3 Wall Effects During Vapor Phase Decomposition of Hydrogen Peroxide

Various reactor wall materials have been tested in an effort to find a material that does not interfere with measuring vapor decomposition rates. Typical materials tested are Pyrex[®] glass or quartz (silica).

A study of the heterogeneous radical decomposition of hydrogen peroxide vapor discovered the accumulation of HO_2 radicals in the gas phase during the decomposition of H_2O_2 on surfaces of Pyrex[®] glass or silica [751]. It was found that for short contact times (10^{-2} s) and low pressures (of the order of several hundred Pa), the decomposition of H_2O_2 occurred mainly on the external surface. An activation energy of 4.6 kJ/mol was obtained for the heterogeneous decay of HO_2 radicals on these surfaces at 473–623 K.

By measuring the decomposition of hydrogen peroxide vapor on Pyrex[®] glass, SiO_2 , $\gamma\text{-Al}_2\text{O}_3$, MgO , or CuO over temperatures ranging from 373 to 623 K for dwell times for the flow to pass through the reactor of 10^{-3} to 10^{-2} s, at a partial pressure of H_2O_2 of 0.072 kPa and a total pressure of the mixture of 0.53 kPa in a carbon dioxide atmosphere, it was shown that the decomposition of H_2O_2 on oxides is autoaccelerated [752]. The effective activation energy of the process in the autoacceleration region was greater than at the fastest rates. The decomposition of H_2O_2 under these conditions was accompanied by the liberation of HO_2 radicals from the surface to the gas phase. The rate of H_2O_2 decomposition and generation of HO_2 radicals increased in the order: glass < SiO_2 < $\gamma\text{-Al}_2\text{O}_3$ < MgO < CuO .

From experimental data on the influence of water on the state of the surface, it was tentatively concluded that clusters are formed on the surface with the participation of adsorbed water molecules, and that the decomposition of H_2O_2 on these clusters proceeds more efficiently than on other surface centers, thus auto-accelerating the process [753]. After the test, holding the system under vacuum resulted in removal of the weakly bound water, breakdown of the clusters, and reversion of the surface to its initial state; see also [754].

4.12.3 Rapid Vapor Phase Decomposition of Hydrogen Peroxide

In order to obtain accurate kinetic rates at high temperatures, one must bring the sample to the test temperature very quickly, otherwise the decomposition that is already taking place while bringing the sample up to test temperature will mess up the results. The fastest and most reproducible method to bring a sample to high temperature is in a shock tube.

One of the most reactive and short-lived intermediates in H_2O_2 decomposition is the hydroxyl-free radical $\bullet\text{OH}$, which has a telltale signature in both emission and absorption spectra or can even cause chemiluminescence in the shocked vapor as it cools off after the shockwave has passed through [755].

Hydrogen peroxide and hydrazine are both energetic monopropellants, and studies of the rapid decomposition of these compounds in the vapor state typically used shock tubes. Some studies deal with both compounds and studied them side-by-side (but not premixed in the same tube).

The thermal dissociation of H_2O_2 , highly diluted with argon, was investigated in a shock tube [756]. The unimolecular dissociation of H_2O_2 near the low-pressure limit was investigated by an ultraviolet absorption technique, which gave

$$k_4 = 10^{16.5} \exp(-43000/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

between 950 and 1450 K. Experiments at 2.02 MPa (20 atm) indicated the beginning of the fall-off region. In addition to H_2O_2 spectra, light absorption corresponding to an unknown species that forms and is consumed again during the reaction, possibly due to HO_2 , was observed around 2300 Å.

A study of the mechanism and the reaction rates of the hydrogen peroxide decomposition for temperatures in the range of 1000–1400 K reported the activation energy for hydrogen peroxide decomposition [757, 758]. The high gas temperatures required for the experiments were obtained by means of a shock tube apparatus, which was a pressure-driven type having a driver section of 3.95 m (13 ft.) and a driven section of 7 m (23 ft.) Helium-air mixtures were used as the driver gas, while 3 vol-% hydrogen peroxide-argon and 3 vol-% hydrogen peroxide-nitrogen mixtures were the two test gas mixtures used at 5.3 kPa (40 mm Hg). The shock tube, made of 316 stainless steel, was found to catalyze the heterogeneous decomposition of H_2O_2 and had to be passivated by passing H_2O_2 vapor through for several hours prior to each test. The activation energy of H_2O_2 decomposition was 208 kJ/mol (49.8 kcal/mol) in argon and 223 kJ/mol (53.3 kcal/mol) in nitrogen. This is in good agreement with literature data reporting this number as 48 kcal/mol. This is close to the energy required for breaking an O—O bond in the HO—OH molecule (217 kJ/mol = 52 kcal/mol).

High concentrations of short-lived $\text{HOO}^\bullet$ free radicals are formed as intermediates during the thermal decomposition of H_2O_2 . With sensitive instrumentation, an electronic spectrum of the free radical could be detected [759]. The thermal decomposition of H_2O_2 in argon as carrier gas has been studied in reflected shockwaves at $950 < T < 1450$ K. In addition to the H_2O_2 absorption continuum, a second continuum was found at $2200 < \lambda < 2800$ Å, which has been attributed to $\text{HOO}^\bullet$. The time dependence of this second absorption continuum agrees well with predictions for the $\text{HOO}^\bullet$ decay time under a wide variety of conditions. The absorption coefficient of $\text{HOO}^\bullet$ can be estimated from measurements taken during the decomposition of H_2O_2 .

A study of the mechanism of the reactions of hydrogen peroxide in the gas phase gave agreement with the experimental data within a broad range of conditions [760]. The reactions of hydrogen peroxide may slow down the rate of combustion of hydrogen but may be neglected at temperatures greater than 1000 °C.

Because of the large amount of experimental data and theoretical analysis available, the dissociation of hydrogen peroxide has become a textbook model case for simple unimolecular bond fission processes. Detailed and simplified statistical adiabatic channel calculations of specific rate constants $k(E, J)$ and product quantum state distributions for the simple bond fission reaction $\text{HOOH} \rightarrow 2^\bullet\text{OH}$ were compared with measurements of state-resolved dissociation rates, product state distributions, $^\bullet\text{OH}$

recombination rates, and thermally averaged rate coefficients [761]. A simple modification of phase space theory based on a statistical adiabatic channel model successfully predicted product state distributions and rate constants.

Hydroxyl-free radical $\text{HO}^\bullet$ concentration-time profiles were recorded during the thermal decomposition of H_2O_2 in shockwaves between 930 and 1680 K by monitoring resonance absorption near 308.4 nm [762]. The results were analyzed with respect to the reactions

and

Above 800 K, reaction (1) showed a strong increase of the rate constant with temperature. Over the range $240 \leq T \leq 1700$ K, the apparent rate constant was represented as

$$k_2 = 1.7 \times 10^{18} \times \exp(-14800 \text{ K}/T) + 2.0 \times 10^{12} \exp(-215 \text{ K}/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

The rate constant k_3 decreased from a value of 2.0×10^{13} at 1100 K to a minimum value of 1.1×10^{13} at 1250 K, and rose again to a value of $4.5 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 1600 K. The anomalous temperature dependences of k_2 and k_3 suggested mechanisms involving intermediate intermolecular complex formation.

The thermal decomposition of H_2O_2 was studied behind reflected shockwaves using absorption spectroscopy at 215 nm with light from a laser source and at 215, 230, and 290 nm with light from a UV lamp [763]. Due to the improved detection sensitivity for H_2O_2 and $\text{HOO}^\bullet$, rate constants for the reactions

and

could be derived with much better precision than was possible in earlier work. Rate constant minima for reactions (3) and (4) near 800 and 1100 K, respectively, agreed with previous measurements. Falloff curves of reaction (1) near the low-pressure limit were measured in experiments at about 1, 4, and 15 bar. Limiting low-pressure rate constants for reaction (1) of about

$$k_{1,0} = [\text{Ar}] 10^{16.36 \pm 0.23} \exp[-(21962 \pm 608) \text{ K}/T] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

were obtained over the temperature range 950–1250 K. The deviations from the low-pressure limit at relatively low pressures may provide experimental evidence for non-exponential lifetime distributions of dissociative H_2O_2 such as observed in classical trajectory calculations on the *ab-initio* potential of H_2O_2 .

Statistical adiabatic channel model/classical trajectory calculations of the dissociation/recombination dynamics of hydrogen peroxide, $\text{H}_2\text{O}_2 \rightleftharpoons 2\text{HO}^\bullet$, have been performed on an *ab-initio* potential energy surface, providing specific rate constants $k(E,J)$, thermal rate constants $k_\infty(T)$ and lifetime distributions [764]. The thermal high-pressure rate constants for $\text{HO}^\bullet$ recombination agreed with experimental data.

The thermal decomposition of hydrogen peroxide was measured behind reflected shockwaves in H_2O_2 /inert gas mixtures using a sensitive laser diagnostic method for water vapor concentration measurement [765]. In these mixtures, the rate of water formation was predominantly controlled by the decomposition rate of H_2O_2 . Rate determinations were made over a temperature range of 1000–1200 K and a pressure range of 0.9–3.2 atm using either argon or nitrogen as the carrier gases. Good detection sensitivity for water was achieved using the tunable diode laser absorption of water at 2550.96 nm within its ν_3 fundamental band. Hydrogen peroxide decomposition rates were found to be independent of pressure at 0.9 and 1.7 atm and showed only a slight influence of pressure at 3.2 atm. The best fit of the data to the low-pressure-limit rate for H_2O_2 dissociation in the range 1000–1200 K in argon gas was

$$k_1 = 10^{15.97 \pm 0.10} \exp(-21220 \pm 250 \text{ K}/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

Experiments conducted in nitrogen carrier gas showed a relative collision efficiency of argon to nitrogen of 0.67.

Experimental rate coefficients for the thermal dissociation

and the reverse recombination

were combined with modeling results based on an *ab-initio* potential energy surface calculation [766]. The rate coefficients derived from the complementary experimental and modeling results were represented over wide ranges of temperature and pressure, including ranges of interest for practical applications, including limiting low- and high-pressure rate coefficients as well as detailed and simplified expressions for rate coefficients in the falloff range.

The rate of hydrogen peroxide decomposition behind reflected shockwaves in diluted H_2O_2 /Ar mixtures between 930 and 1235 K and at three different pressures (1, 2, and 10 atm) was measured using mid-IR absorption of H_2O_2 near $7.7 \mu\text{m}$ [767]. Under these conditions, the decay of hydrogen peroxide was sensitive only to the decomposition reaction rate, $\text{H}_2\text{O}_2 + \text{M} \rightarrow 2\text{OH} + \text{M}$ (k_1). The second-order rate coefficient at low pressures (1 and 2 atm) did not exhibit any pressure dependence, suggesting that the reaction was in the low-pressure limit. The rate data measured at 10 atm exhibited falloff behavior. The decomposition rates measured can be expressed in Arrhenius forms as follows:

At 1 atm and at 2 atm:

$$k_1 = 10^{(16.29 \pm 0.12)} \exp(-21993 \pm 301/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

and for 10 atm:

$$k_1 = 10^{(15.24 \pm 0.10)} \exp(-19955 \pm 247/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

See also [768, 769].

4.12.4 Ignition Limits of Vapor Phase Decomposition of Hydrogen Peroxide

Explosive characteristics of hydrogen peroxide vapor at atmospheric and subatmospheric pressures, including values for the ignition limit over this pressure range and the effect of the nature of diluent gases and method of initiation on the limit have been reported [770, 771]. In continuation of these studies, ignition limits were determined over the pressure range of 101 to 655 kPa (14.7 to 95 psia) [772]. The term “ignition limit” was defined as the minimum concentration of hydrogen peroxide in a vapor mixture,

Figure 51: Ignition limit of hydrogen peroxide/water vapor at pressures above atmospheric pressure. (Reprinted and modified from [772], with permission from © 1959 American Chemical Society; permission conveyed through RightsLink.)

under specified conditions, below which powerful external ignition cannot initiate a self-propagating reaction. The concentration of H_2O_2 in the vapor phase of a high-pressure boiler pressurized with nitrogen was allowed to gradually increase until ignition by a high-voltage spark caused ignition in a 5-cm (2-in.) diameter bulb. Upon ignition, the temperature in the ignition bulb jumped sharply and extensively. Between 2- and 6-atm pressure, the ignition limit was found to be constant at 20.7 mol-% H_2O_2 in the vapor. At atmospheric pressure, the limit was found to be 25.6 mol %, slightly lower than the previously established value of 26.0 mol-% (Figure 51).

4.13 Strand Burning, Droplet Burning, and Explosion Limits of Hydrogen Peroxide

4.13.1 Flame Speed of Stabilized Hydrogen Peroxide Vapor Flames

Hydrogen peroxide vapor decomposition flames can be stabilized on a burner even in the absence of a combustible fuel. The energy of the decomposition flame is derived solely from the monopropellant-mode exothermic decomposition of the energetic chemical. The hydrogen peroxide decomposition flames are not very luminous since the temperatures are relatively low, and there are no species in the flame that emit radiation in the visible range.

For the decomposition above the liquid, flames were obtainable over the liquid of lower concentrations only at temperatures close to the boiling point of the liquid. At the higher concentrations, flames could be obtained and sustained over a considerable range of liquid temperatures. Hence, only at these higher concentrations was it possible to map the effect of liquid temperature on the flame velocity. Flames were sustained in the range of 71.2 to 100 mol-% of H_2O_2 . Flames may be obtained at boiling liquid concentrations as low as 69.8 mol-%. If the tube diameter was increased, no apparent influence was observed on the flame velocity except when working at high concentrations [773].

The flame speed of H_2O_2 decomposition flames at reduced pressures from 50, 72, and 101 kPa (0.5, 0.72, and 1 atm) was measured using a Bunsen burner method [774, 775]. A plot of the logarithm of the product of the square of the burning velocity and the pressure versus the reciprocal flame temperature gave a good correlation between the data obtained here at all pressures. Another graph, plotting the product of the square of the burning velocity and the pressure versus the strand burning velocities above liquid solutions of H_2O_2 , gave also an almost linear relationship. This covered a 200-fold range of burning velocities. In another graph, the burning velocity was also correlated with the quenching distance and some approximate blowoff and flashback limits of the vapor flame. The flame speed dependence on vapor temperature followed the kinetics expected for a first-order reaction with an activation energy of 146 kJ/mol (35 kcal/mol). Table 48 and Figure 52 give the flame speed as a function of the H_2O_2 concentration. The vapor temperature was always kept 9 °C above the prevailing boiling point in order to prevent condensation; see also [776, 777].

Table 48: Flame speed of H_2O_2 vapor at 101 kPa.

H_2O_2 Concentration, mass-%	Flame speed, m/s

4.13.2 Strand Burning Rates of Liquid Hydrogen Peroxide

The strand burning regression rate of liquid H_2O_2 was measured in quartz tubes [778]. The liquid regression rate agreed with the vapor flame speeds. The mass consumption rate (normalized by the cross-sectional area of the burning strand) as summarized in Table 49 agreed with the calculated vapor flame speed summarized in Table 50.

The ignition temperature of H_2O_2 vapors on a hot surface was measured for different materials [778]. This information is useful for the safe design of hydrogen peroxide distillation systems where hot spots must be avoided by all means; see also [779].

The strand burning velocity of 90% H_2O_2 at 0 and 30 psig was measured in 8-mm ID tubes by Rocketdyne [780]. Such tubes were selected because the literature appeared to indicate that wall effects were negligible in a container of that size. Ignition was accomplished with a nichrome resistance wire heated to a bright red hot 1144 to 1255 K (1600 to 1800 °F). Ignition could not be obtained in either the vapor or liquid phase when the bulk liquid temperature was below 383 K (230 °F) at 0 kPa gauge

Table 49: Mass consumption rates during strand burning of H₂O₂ solutions at sea-level atmospheric pressure.

(0 psig) or below 390 K (242 °F) at 206 kPa gauge (30 psig). Ignition could not be accomplished at 688 kPa gauge (100 psig) even at a bulk liquid temperature of 439 K (330 °F). The burning rates obtained are summarized in Table 51 and illustrated in Figure 53.

4.13.3 Strand Burning Rates of Liquid Hydrogen Peroxide Mixtures

A ternary PERSOL-1 blend consisting of 46% AN, 38% H₂O₂, and 16% H₂O had a very low freezing point of 248 K (−25 °C) and a density of 1.415 g/mL and was evaluated as an oxidizer for a non-hypergolic non-toxic fuel. Attempts to measure strand burning rates of PERSOL-1 at ambient temperature, 313 and 333 K, in a windowed constant pressure bomb failed because the oxidizer failed to propagate and reaction was quenched as soon as the electric power to the heated nichrome igniter wire was turned off [781].

Table 51: Strand burning rates of 90% hydrogen peroxide in 8-mm ID tubes.

4.14 Droplet Burning Rates of Liquid Hydrogen Peroxide

Hydrogen peroxide droplets injected into and suspended in a flow of hot gas will evaporate and decompose rapidly. This happens in the zone close to the injector of bipropellant rocket engines and in the second stage of catalyst-free monopropellant rocket engines with a pilot reactor. The hot gas the droplets are injected into could be created by a pilot reactor (with catalyst), which would be started and brought up to steady-state temperature before the H_2O_2 is injected into a downstream hollow secondary reaction chamber.

A liquid spray of high concentration hydrogen peroxide was injected into a hollow chamber holding a stream of peroxide decomposition products at pressures ranging from 2.07 to over 5.5 MPa (300 to over 800 psia) [782]. A decomposition efficiency was calculated based on the ratio between measured chamber pressure and chamber pressure predicted by equilibrium chemistry calculations. Experimental parameters included concentration of the liquid H_2O_2 , residence time, mass, and momentum ratio between the decomposition stream and the injected liquid, and injection area. Decomposition efficiencies ranging between 10 and 90% were achieved. A limited number of highly accurate differential pressure measurements were made to determine local axial pressure gradients. The results indicated that liquid mass fraction was inversely proportional to decomposition efficiency, while the residence time and hydrogen peroxide concentration were directly proportional. Aqueous hydrogen peroxide solutions with two different weight concentrations, 90 and 98%, were used as secondary flows. The first 22 tests, called preliminary tests, were performed simply to determine an efficiency map and the flooding limits. One of the main goals of the preliminary tests was to map the decomposition efficiency of injected liquid with different ratio between mass-weighted decomposed gas and injected liquid.

In continuation of these studies, a well-instrumented subscale combustor was used to measure axial pressure profiles [783]. The results were compared to 1-D numerical modeling to determine the axial energy release profile in the combustor. Again, a liquid spray of high concentration hydrogen peroxide (HTP) was injected into a gas stream of decomposed hot products of HTP from a catalyst bed at chamber pressures ranging from 1.38 to 6.2 MPa (200 to 900 psia). The effects of area variation, mass and enthalpy addition, heat transfer, and frictional effects were evaluated. A study of design parameters (injector design, contraction ratio, and chamber length) and operating parameters (mass flow rate fraction, gas-to-liquid ratio, HTP concentration, gas-to-liquid momentum ratio, and residence time) helped to evaluate the combined effects on the thermal decomposition of the injected HTP. These measurements later helped to develop a model of HTP droplet evaporation in hot gas flows in a rocket engine [784, 785] (*Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide Monopropellants”).

A one-dimensional model was developed to investigate the thermal decomposition of rocket-grade HTP injected as a fine droplet spray into a stream of previously

decomposed HTP products [786–789]. The model assumed steady, one-dimensional adiabatic flow and included basic mass balances, droplet evaporation, gas-phase decomposition kinetics, droplet dynamics, and control volume conservation laws. The code was adjustable for HP percent concentration for both main and secondary flows, mass flow rates for both flows, and the initial temperature of each. Results were shown to be consistent with prior experimental measurements. Additional parameters are initial droplet size, secondary injectant flow, mass velocity in the primary stream, HTP concentration, and initial liquid temperature on the decomposition process. In general, results indicated unacceptably-long decomposition distances assuming 90% HP decomposition products in the primary stream. Using 98% HTP showed some improvement due to the enhanced decomposition temperature of this fluid as compared to 90% HTP.

An alternate approach to the catalytic decomposition for HTP decomposition is thermal decomposition, where no catalyst is required (at least not in the downstream part of the reactor). If the rate of thermal decomposition can be controlled, the ensuing technology will prove to be a viable and inexpensive alternative to using catalysts. A kinetic and CFD detailed model of the steps for HTP decomposition over a wide range of temperatures and pressures combined with CFD simulations of a dual-chamber (catalytic-non-catalytic) was applied to a HTP decomposer described in a patent by Pratt & Whitney [790] and was based on the fundamental kinetic rates for 27 reactions involving O and H [791]. Computation results were shown for injecting different concentrations of H_2O_2 (10, 30, 40, 50% H_2O_2) into the hot gas delivered by the primary reactor. A similar model can be applied to model decomposers for generating a stream of atomic oxygen in a COIL laser.

It was planned to conduct the fundamental research necessary to understand the purely thermal decomposition kinetics of HTP and its interactions with common stabilizers, in order to design a practical non-catalytic thermal decomposer [792, 793]. The utilization of HTP as rocket propellant could be greatly simplified by using a thermal decomposer rather than a catalyst bed for decomposition. This would require a thermodynamic analysis of self-reactivity and a reaction kinetics model for thermally decomposing HTP, and stability and inhibitor modifications thereof, that could serve as the basis of a conceptual design of a practical thermal decomposer.

4.15 Analysis of Hydrogen Peroxide

In using hydrogen peroxide and other rocket propellants, the analyst will face different tasks. The most important one is the assurance that hydrogen peroxide that has been stored for a while still meets the specification requirements for assay. The incessant decomposition of hydrogen peroxide, as slow as it may be, is a continuing concern for rocket engineers. Other analytical tasks relate to the detection of traces of H_2O_2 vapors in the atmosphere at workplaces and in the wastewater leaving the test

sites. For many H_2O_2 applications, such as in catalytic monopropellant reactors, the stabilizer content is troublesome because too much stabilizer may foul the catalyst. The types of stabilizer and the amount used may need to be analyzed from time to time, in particular each time after switching H_2O_2 suppliers. Organic contaminants in H_2O_2 may be residuals from the manufacturing process (if not using an electrolytic method), or they may have been added as stabilizer (oxine, citric acid). Other organic contaminants may have been introduced inadvertently and leached from gaskets or transfer hoses. In either case, we need methods to analyze organics in hydrogen peroxide.

Military procurement specifications specify not only the required assay and purity levels, but also contain recommended or required methods on how to perform the analysis.

The previously quoted books and monographs on hydrogen peroxide contain chapters on analytical methods [2, 18]. Manufacturers' product information bulletins may also provide additional information on analytical methods [794]; see also [23, 795].

4.16 Assay of Hydrogen Peroxide

Although MIL-P-16005D recommended determination of H_2O_2 assay by ceric sulfate titration, a survey of the industry indicated that as of the 1960s, most laboratories preferred H_2O_2 assay determination by a permanganate titration because of the ease in identification of the end point by color change. However, all laboratories can perform the ceric sulfate titration with equivalent accuracies.

The fastest non-chemical method to determine the H_2O_2 content in aqueous solutions up to very high H_2O_2 concentrations is the measurement of the refractive index [796]. Density and refractive index methods for determining hydrogen peroxide in cleaning baths were compared to the potassium permanganate titration method. The refractive index method was shown to be rapid and simple and required only a few drops of sample. This method exhibited a $\pm 0.14\%$ H_2O_2 standard deviation for a single measurement and an average bias of -0.002% H_2O_2 compared to the titration method. The refractive index method has been implemented at a process line for fast results at a substantial cost savings. Refractive index data for 293 and 298 K were already summarized in Tables 20 and 21.

Attempts to determine the assay of H_2O_2 by measuring the density with a spindle or a pycnometer are often thwarted by the small bubbles forming on the glass surface.

Another method to determine the assay of H_2O_2 solutions between 70 and 95% is to measure the adiabatic decomposition temperature in a catalytic reactor and compare the temperature to the theoretically predicted or empirically derived temperature [795, 797]. This apparatus does not need much electricity and can be operated under

field conditions. It may take up to 16 min before stationary reactor temperature conditions are achieved. The concentration can be calculated from the following equation:

$$t_{\text{ad.}} = 2540c - 1545 + 2.00(t_0 - 20)$$

where $t_{\text{ad.}}$ = adiabatic decomposition temperature, °C, c = mass-% H_2O_2 , and t_0 = initial temperature of liquid H_2O_2 , °C. One may have to carry out a calibration series and apply a corrective factor, depending on the apparatus used. The standard deviation can be as low as 0.05% H_2O_2 absolute.

A comparison fluid density measurement, refractive index measurement, and the potassium permanganate volumetric methods of analysis ranked the methods by accuracy in the sequence Manual KMnO_4 Titration > Refractive Index > Density, with the refractive index method having the best precision (± 0.02 mass-% H_2O_2) [437, 798]. The recommended technique of HTP assay is the permanganate titration method, which yields credible results over time of HTP storage and is consistent with supplier certification data and the historical analysis database. Results of an assay by refractive index tend to be approximately 0.8 mass-% lower than for KMnO_4 titrations with 98% HTP but is judged as equivalent when 90% HTP is analyzed and compared to the permanganate method. The refractive index method for HTP concentration offers superior precision and ease and convenience of analysis. Results from densitometry data were unreliable, with variability likely due to the less mature measurement techniques used at that time. Densitometry is not as convenient a technique as the other two methods but can be shown to provide equivalent results to either alternate tests if using accurately calibrated pycnometers and stable temperature control. The use of modern state-of-the-art density meters, such as the Mettler DE45, may afford acceptable results but may require additional method development effort.

The NMR transverse relaxation time T_2 of aqueous H_2O_2 solutions depends on the rate of exchange of the spin-bearing protons between H_2O_2 and H_2O molecules. For pulse separations exceeding the inverse exchange rate, this value becomes a constant, depending only on the proton exchange time and the magnetic field strength. This exchange time depends in a non-analytical way on the concentration of H_2O_2 and on the pH value. Thus, a measurement of T_2 and pH allows the inversion of the data for the non-invasive quantitative determination of the H_2O_2 concentration [298, 449]. The method was applied to measure the time profile of a heterogeneously catalyzed H_2O_2 decomposition using commercial catalyst pellets by monitoring the reactant concentration and the effective diffusion coefficient of the liquid in the vicinity of the pellet or in a defined closed volume. The decrease of the concentration during the course of the reaction was monitored, and the long-time deactivation of the pellet can be demonstrated using this technique. This is a new method for contact-free and non-invasive on-line monitoring of H_2O_2 concentrations.

The mass fraction of hydrogen peroxide can be determined by a titration method in accordance with the Chinese National Standard GB 1616-2003 [799]. The uncertainty

caused by the potassium permanganate standard solution is the worst contributor to inaccuracies.

4.16.1 Analysis of Traces of Hydrogen Peroxide Vapors in the Atmosphere

There are numerous contact and non-contact, remote sensing methods to analyze H_2O_2 in the atmosphere on Earth and other planets. This is done to identify the role that H_2O_2 plays in natural processes (in particular as the result of increasing UV radiation passing through a damaged ozone layer) in the atmosphere, as well as H_2O_2 formed in the wake of industrial pollution. These methods are also useful in monitoring the air in workplaces, such as rocket test sites and launch sites where personnel may be exposed to H_2O_2 vapors, and occupational hygiene threshold limit values must not be exceeded.

The following method arose from the need to analyze for more than traces of H_2O_2 in the air of surgical equipment manufacturing and packaging facilities. The widespread use of hydrogen peroxide as a clean, non-residue disinfectant is based on its ability to kill harmful bacteria and not leave any residues. Hydrogen peroxide vapor is used in a method like ethylene oxide or ultraviolet light to prevent bacterial contamination during the packaging and sealing of sterile surgical supplies and dispensing of IV solutions. Like ethylene oxide, hydrogen peroxide vapor in these industrial settings is an explosion hazard and needs to be closely monitored. A calorimetric gas sensor for the detection of vaporized H_2O_2 in aseptic filling processes was built up on a polyimide foil as substrate material in order to optimize the sensor response behavior [800, 801]. These sensors are built up in the form of a differential setup of a catalytically active and a passive temperature-sensitive structure. The sensor was catalytically activated with a dispersion of manganese(IV) oxide. The calorimetric gas sensor possessed a linear response behavior with a sensitivity of $7.15\text{ }^\circ\text{C}/(\text{vol.}\% \text{H}_2\text{O}_2)$ in a H_2O_2 concentration range from 0 to 8 vol.-%.

Tunable diode laser absorption spectroscopy is one of the most sensitive methods to determine hydrogen peroxide vapor in ambient air with sub-ppb_v (parts per billion by volume) detection limits for fast measurement times of the order of minutes [802]. Calibrating the instrument with constant vapor concentrations of a labile substance is not easy. In atmospheric chemistry, the mixing ratio usually refers to the mol ratio, which is defined as the amount of a constituent n_i divided by the total amount of all other constituents in a mixture. Ambient air monitoring with the tunable diode laser system indicated that the hydrogen peroxide mixing ratio was often smaller than 0.3 ppb_v. Five-minute average mixing ratios of up to 2.9 ppb_v were measured at sites in southwestern Ontario, Canada, during the summer months of 1984 and 1985, while the highest 1-h average value observed was 2.1 ppb_v.

Much higher concentrations of H_2O_2 are encountered where H_2O_2 is vaporized to sterilize hospital rooms, air ventilation ducts, or surgical equipment. On-line and essentially continuous measurements of hydrogen peroxide vapor in the presence of water vapor can be made using near infrared (NIR) spectroscopy using fiber optic cables

to transmit infrared radiation between the remote location where measurements must be made, e.g., a sterilization chamber and the NIR instrument located behind barriers [803]. Hydrogen peroxide absorbs selectively at about 1420 nm, where water vapor also absorbs, but the absorbance at 1420 nm can be corrected for water by taking separate vapor measurements at remote wavelengths (1350–1400, 1830–1900, or 915–950 nm) where H_2O_2 is transparent.

The Draeger short-term detector tubes have proven to be a very cost-effective and reliable way to measure toxic gases and vapors in the workplace. The Draeger Hydrogen Peroxide tube, Catalogue Part No. 81 01 041, measures 0.1–3 ppm H_2O_2 .

The Draeger CHIP is a self-contained unit that has a pump and a digital readout. Each disposable chip contains ten measurement capillaries filled with a substance-specific reagent system. The reactive preparations necessary for detection are kept in hermetically-sealed glass capillaries until needed. When the chip is inserted into the analyzer, all information required for detection is transferred to the analyzer by means of a bar code:

- type of gas
- measuring range
- measuring time
- parameters for the calibration function
- required flow rate

The analyzer records the measurement effect optoelectronically, thereby eliminating human error in reading a color scale. In the CHIP Measuring System, miniaturization has resulted in a reduction in the sample volume necessary for a measurement (compared to the manual bellows pump with ten strokes). For a typical measurement, only 30 mL of air is needed for a measuring time of approximately 2 min and a flow of 15 mL/min. The power needed for operation of the analyzer is provided by four AA batteries. After inserting the chip, an optical system calculates the number of remaining measurements still available on the chip being used and displays this together with the gas type and the measuring range. Up to 50 measurement results can be stored in the machine with the name of the measured substance, the concentration, date and time of the measurement, and a code letter to help identify the measurement location.

For a more accurate, continuous monitoring of hydrogen peroxide vapors in air, the H_2O_2 (XS) electrochemical sensor with a Draeger Pac III apparatus has a range of 0–20 ppm H_2O_2 , a resolution of 0.1 ppm, and the Draeger Part Number is 68 09 170.

The Dräger X-am 5100 was specifically developed for the detection of hydrogen peroxide or hydrazine reactive gases in air. The X-am 5100 with the sensor XS is particularly suited to applications such as monitoring H_2O_2 during the bleaching process in pulp and paper production, monitoring sterilization units used in the medical field, and monitoring hydrogen peroxide at the workplace.

Hydrogen peroxide vapor concentrations in sterilization chambers for surgical equipment or beverage cartons can be monitored by a calorimetric gas sensor using

manganese(IV) oxide as the catalyst [804]. XPS was used to unravel the surface chemistry prior to and after exposure of the catalyst to hydrogen peroxide vapor at elevated temperature. The surface characterization revealed a change in oxidation states of the metal oxide catalyst after exposure to hydrogen peroxide.

4.16.2 Analysis of Small Concentrations of Hydrogen Peroxide in Aqueous Solutions

The need to analyze for small concentrations of hydrogen peroxide in water may arise when analyzing rinse waters from HTP propellant tanks before discharging them into surface waters or sewers or sending them to holding ponds for neutralization. Some passivation procedures require the rinsing to continue until all H_2O_2 is removed from the tank. In this case, it would be good to have an instant readout from a probe dipped into the outgoing rinse water to decide when the rinse is complete. The turnaround time for the analysis of grab samples would just be too long. Similar, but rare occasions arise where HTP has been spilled accidentally and washed down with copious amounts of water. Then the next question is how much H_2O_2 remains in the impounded deluge water, and how it should be treated before it can be released.

Hydrogen peroxide can be an oxidizing agent or a reducing agent. Potentiometric and amperometric electrical analysis methods have been developed to analyze small concentrations of H_2O_2 in aqueous solutions in the absence of interfering agents.

4.16.3 Analysis of Hydrogen Peroxide in Wastewater

The easiest-to-perform qualitative test for traces of hydrogen peroxide in aqueous solutions uses a solution of titanyl sulfate in dilute sulfuric acid. Titanyl ions form an intensely yellow complex with hydrogen peroxide:

The test can be sensitive to H_2O_2 concentrations in water as low as 1 to 2 ppm. It is best performed by acidifying the sample with 6-N sulfuric acid and adding several drops of a 10% solution of titanyl sulfate in 6-N sulfuric acid. The test is specific for H_2O_2 , and there are few interferences. Peroxydisulfate or ozone do not interfere, and the color does not fade as quickly as that produced by organic reagents for H_2O_2 .

A simple and rapid method for the spectrophotometric determination of hydrogen peroxide used potassium titanium(IV) oxalate [805]. The method can be used to measure peroxide concentrations down to about $10\text{ }\mu\text{M}$ (0.3 mg/kg) under the most favorable conditions. A variety of complexing and reducing agents, and catalysts of peroxide decomposition, known to interfere with the alternative iodide method for peroxide determination, had no effect. Fluoride was found to interfere.

For quantitative determination of hydrogen peroxide in dilute aqueous solutions and in the absence of other reducing materials one will best use the manganometric volumetric titration.

The source of the dioxygen formed in this reaction was unclear initially in the early years of H_2O_2 chemistry. It has now been shown that the dioxygen comes from the H_2O_2 , and that the oxygen from the KMnO_4 ends up as water.

In order to carry out a manganometric titration, the sample containing approximately 350 mg H_2O_2 is diluted with 50 to 100 mL of 3-N (25%) sulfuric acid and titrated with 0.5-N KMnO_4 solution to a persistent purple color. Another redox titrant that can be used for this analysis is cerium(IV) sulfate, which is more stable for storage as a solution. KMnO_4 solutions often change their titer during storage and need to be recalibrated by titration with sodium oxalate. Another volumetric method adds an excess of potassium iodide to the acidified sample, allows it to stand for 5 min, and titrates the liberated free iodine with standardized sodium thiosulfate solution, adding starch indicator only toward the end of the titration.

The volumetric methods are not sufficiently accurate to determine assays of highly concentrated H_2O_2 . Small amounts of H_2O in H_2O_2 are better analyzed using physical methods instead of wet chemistry methods.

The oxidation of iron(II) by hydrogen peroxide is a convenient source of free hydroxyl radicals (Fenton's reagent). The end products are iron(III) and water

In looking for a method for continuous analysis of flowing H_2O_2 solutions in a flow-through cell, polarography was evaluated as one of the candidate methods [806] using a dropping-Hg electrode and a stationary Pt electrode. The diffusion current increased linearly with peroxide concentrations up to 0.15% with 0.1-N KCl as supporting electrolyte. At higher concentrations the electrode became erratic. When a fixed Pt electrode was used, the diffusion current increased linearly with concentrations up to 0.9%. Rotating Pt electrodes gave unsatisfactory results. Since the limiting current in solid microelectrodes is dependent both on dissolved O_2 and peroxide content, they are of little value in continuous analysis of flowing H_2O_2 solutions.

4.16.3.1 Volumetric Methods

The assay of hydrogen peroxide can be determined by titration with cerium(IV) sulfate solution with ferroin indicator as described on pages 9–13 of a US Army analytical procedure [807].

4.16.3.2 Electrical Potentiometric and Polarographic Methods

Many of the electrodes used for electrochemical analytical methods will also serve as electrodes for fuel cells. In fuel cells, one wants to keep the output voltage constant, thus one must maintain a constant H_2O_2 concentration in the cell. In analytical applications, the concentration of H_2O_2 is unknown, and one must wait for the voltage potential to stabilize before one can take a reading. In either case, the electrodes must not be such good catalysts that they decompose the H_2O_2 prematurely even while no

current is flowing. In other applications, one can deliberately coat the electrode with a catalytic layer and then measure the potential of the oxygen gas evolved.

Hydrogen peroxide can be polarographically assayed by anodic oxidation. This method is very sensitive but lacks specificity for peroxide in the presence of other redox-active substances that undergo anodic oxidation, such as ascorbic acid. However, if H_2O_2 is first catalytically decomposed to O_2 and H_2O , then the O_2 can be assayed polarographically using an oxygen electrode. Furthermore, specificity for just oxygen can be obtained by placing a hydrophobic membrane over the O_2 electrode. Polarographic measurement of O_2 or H_2O_2 is the basis for several enzyme-coupled electrodes. An inorganic catalyst electrode was made by covering an oxygen electrode with a membrane that catalyzed the breakdown of hydrogen peroxide to oxygen [808]. This electrode is similar in principle to an enzyme electrode, but has better stability gained by using an inorganic catalyst instead of catalase. Of the many different metal compounds that were tested, only the compounds of manganese, cobalt, or ruthenium showed high catalytic activity.

Hydrogen peroxide sensors can use carbon-based electrodes loaded with perovskite-type oxides [809] or Prussian Blue-based artificial peroxidase [810]. Other electrodes are made from carbon nanotubes [811].

Some of the electrodes for analysis of H_2O_2 in air or in water can be miniaturized and mounted on a semiconductor chip. A hydrogen peroxide sensor was developed based on an electrolyte MOSFET (E-MOSFET), and different types of redox materials were tested as gate materials with respect to sensitivity and detection limit [812]. E-MOSFETs with electro-active gate materials such as iridium oxide, potassium ferric ferrocyanide, and osmium polyvinylpyridine containing a peroxidase enzyme were tested with respect to their sensitivity, detection limit, and stability. The determination of hydrogen peroxide is based on the oxidation of the iridium(III) oxide by hydrogen peroxide

Another sensor was based on osmium-polyvinylpyridine (Os-PVP) doped with horseradish peroxidase. An enzyme catalyst can be used as the gate material, or it can be immobilized into a gate membrane material. Horseradish peroxidase is known as an enzyme that can selectively catalyze the reduction of hydrogen peroxide, and it can be immobilized in the cross-linked redox polymer OsPolyvinylpyridine (Os-PVP), which is a non-diffusional mediator. The operating range of three different electrode materials for H_2O_2 detection was:

Ir oxide	$10^{-4} - 10^{-1} \text{ M}$
Prussian Blue	$10^{-5} - 10^{-3} \text{ M}$
Os-PVP horseradish peroxidase	$10^{-7} - 10^{-5} \text{ M}$

A fiber-optic sensor sensitive to hydrogen peroxide was based on the electrostatic layer-by-layer self-assembly method using Meldola's blue and a catalyst hemin de-

posited in a polymeric structure formed by polycyclic aromatic hydrocarbon PAH^+ and PAA^- [813]. The concentrations that could be detected ranged between 10^{-7} and 10^{-1} M, and recovery of the sensor after immersion in a reducing agent was quick.

4.16.3.3 Electrical Amperometric Methods

Hydrogen peroxide could be analyzed using electrodes of ruthenium/rhodium deposited as thin layers on gold foils when the cathodic reduction at potentials was lower than +170 mV, or the anodic oxidation was at higher potentials [814]. Under flow injection conditions H_2O_2 was detected between 1 and 1000 μM H_2O_2 at a potential of -100 mV and between 2 and 500 μM H_2O_2 at a potential of +250 mV vs. $\text{Ag}/\text{AgCl}/0.4\text{-M}$ KCl .

4.16.3.4 Electrical Coulometric Methods

A direct coulometric determination of hydrogen peroxide with electrogenerated hypobromite is both sensitive and precise [815]. The end point is determined amperometrically with two polarizable electrodes. As little as 1 μeq of peroxide was determined with a 0.2% error.

A procedure was developed for the determination of hydrogen peroxide by controlled-potential coulometry [816]. The method involved the oxidation of hydrogen peroxide at a platinum electrode at +0.93 volt versus SCE (saturated calomel electrode) in a supporting electrolyte of 1-M sulfuric acid, a complete electrolysis required 3 to 2 min. Moderate amounts of cations, common organic stabilizing agents, peroxydisulfate ion, and chloride ion did not interfere. The heterogeneous, catalytic decomposition of hydrogen peroxide at the platinum electrode at open circuit was nearly as rapid as the electrolytic oxidation. In the range of 0.1 to 2 mg of hydrogen peroxide in a solution volume of less than 5 mL the relative standard deviation of the determination was $\pm 0.1\%$.

4.16.3.5 Spectrophotometric Methods

Infrared Spectrophotometric Methods

Near infrared spectroscopy has been used for the determination of hydrogen peroxide in antiseptic pharmaceutical preparations where it is found in concentrations of about 3.0% [817]. Standard solutions containing hydrogen peroxide in the range 0–10% were prepared and analyzed. Absorbance spectra in the wavelength range from 850 to 1800 nm were obtained using a transreflectance probe with an optical path length of 1 mm. The region from 1400 to 1550 nm is dominated by a strong absorption band from water, the first overtone of O—H. A decrease in the absorption in this region is observed in the presence of H_2O_2 , while an increase in the absorption is noted in the region from 1550 to 1750 nm. The method was evaluated by using prepared and commercial samples of pharmaceuticals containing H_2O_2 in the range from 1 to 20%, resulting in a mean square root standard error of 0.05%.

Midinfrared attenuated total reflection (ATR) spectroscopy was used to measure the concentration of hydrogen peroxide in aqueous matrices [818]. The performance of different ATR crystals mounted in flow cells was investigated in the presence of aqueous hydrogen peroxide solutions. Quantitative determination was achieved by evaluation of specific OH stretching and deformation vibrations with linear correlation between peak areas or peak heights and hydrogen peroxide concentration in the range of 1–10% H₂O₂.

Raman Spectrophotometric Methods

A handheld Raman spectrometer can be used to determine hydrogen peroxide concentration in aqueous solutions in a very short time using relative peak heights of the strongest peroxide (876 cm⁻¹) and perchlorate (932 cm⁻¹) bands with sodium perchlorate as an internal standard [819]. This method provides a very rapid technique to allow the determination of hydrogen peroxide concentrations in the field, for example, at suspected improvised explosives manufacturing sites.

Chemiluminescence Methods

Luminol (5-amino-2,3-dihydro-1,4-phthalazinedione, 3-aminophthalic hydrazide) reacts with oxidants like hydrogen peroxide in the presence of catalysts [hemoglobin, iron(II)hexacyanide] under the emission of light. The light intensity is proportional to the amount of hydrogen peroxide, even if it is present in only very low concentrations. The chemiluminescence method can be combined with chromatographic methods and used as a means of detecting hydrogen peroxide peaks in the effluent.

The optimum conditions of high-performance liquid chromatography combined with luminol chemiluminescence detection were established for the determination of hydrogen peroxide at picomol levels using a cation exchange gel column [820]. A gel column with distilled water as the mobile phase allowed a good separation of H₂O₂ without causing any irreversible binding of H₂O₂ to the column surface. The detection limit and the quantification limit of H₂O₂ were 4 and 6–600 pmol, respectively.

A chemiluminescence method with a subnanomolar detection limit for the determination of H₂O₂ is based on the catalytic [cobalt(II)] oxidation of luminol by hydrogen peroxide in an alkaline solution [821]. The mixed reagent is optimized for pH and concentration of luminol and Co²⁺. The method has been used to determine the concentrations of H₂O₂ in seawater samples in the open ocean as well as on the continental shelf.

A flow injection type hydrogen peroxide detection system based on chemical photoluminescence spectroscopy had the lowest detectable limit of 0.3 ppb H₂O₂. The relationships between the hydrogen peroxide concentration and luminous intensity were expressed as a linear function and a quadratic function of the H₂O₂ concentration [822]. The dependencies of the chemiluminescent intensity on luminol concentration and pH of the mixed reagent were mainly determined by a balance between OH radical concentration and luminol concentration.

4.16.3.6 Analysis of Stabilizer Type and Content in Stabilized Hydrogen Peroxide

The Constantine and Cain *Hydrogen Peroxide Handbook* [246] gives a useful summary and comparison of various analytical methods for determination of contaminants in HTP, based on interviews with chemists of the analytical laboratories of several HTP producers at that time.

Phosphate

The DuPont procedure for the determination of the phosphate ion is essentially identical to MIL-P-16005D, except that the ether extraction is omitted. The Shell procedure also omits the ether extraction and uses hydrazine instead of stannous chloride to develop the molybdenum blue color [823]. The FMC procedure is somewhat different. FMC reported that attempts to use this procedure (MIL-P-16005D) failed to give valid or reproducible results.

The phosphate content of hydrogen peroxide can be determined by a phosphomolybdate yellow spectrophotometric method measuring absorbance at 460 nm [824]. The minimum detectable content is 0.5 µg/mL.

Tin and Stannate

Both DuPont and FMC suggested the use of a polarographic method for determining tin in contrast to the spectrophotometric technique recommended in MIL-P-16005D. Shell used a spectrophotometric technique, which was different from that in MIL-P-16005D; the stannic tin is extracted into an 8-hydroxyquinoline-chloroform solution at a pH of 0.85, and the tin was determined spectrophotometrically in the chloroform extract. Tin in hydrogen peroxide can be determined by atomic absorption spectrophotometry [825].

Nitrate

Nitrate can be added to HTP as a stabilizer. FMC analytical methods recommended that the heating step with the phenoldisulfonic acid reagent, employed in the determination of the nitrate ion, be increased to 15 min (up from 5 min) to ensure complete contact and nitration of the sample residue. The Shell procedure utilizes a larger sample size and increases the heating time to 10 min.

4.16.3.7 Analysis of Inorganic Contaminants in Hydrogen Peroxide Chloride

At a time when Shell Chemical was still producing HTP, their chemists suggested determination of the chloride ion by the measurement of turbidity with a colorimeter instead of the spectrophotometer specified in MIL-P-16005D [823].

The FMC procedure is a colorimetric method using mercuric thiocyanate and ferric ammonium sulfate [826].

Sulfate

For the determination of sulfate, DuPont recommended the use of a preliminary perchloric acid oxidation to measure total sulfur, instead of only sulfate sulfur. Shell recommended precipitation with barium chloride, stabilization of the suspension by the addition of alcohol and glycerin, and turbidity measurements with a photoelectric colorimeter-nephelometer. FMC also suggested the use of a turbidimeter (rather than the spectrophotometer) and a method that converts SO_4^{2-} to H_2S instead of a caustic addition with BaSO_4 precipitation.

Aluminum

In the spectrophotometric procedure specified in MIL-P-16005D for the determination of the aluminum ion, an aluminum-gelatin buffer solution is used for color formation. The DuPont and Shell procedures suggest the use of 8-hydroxyquinoline and extraction with chloroform for color formation.

Ammonium

In determination of the ammonium ion by spectrophotometry, the DuPont method separates the ammonia from the other contaminants by Kjeldahl-type distillation before color formation. The FMC and Shell procedures essentially agreed with MIL-P-16005D, except FMC suggested that greater accuracy may be achieved by increasing the sample size from 10 to 50 mL.

4.16.3.8 Analysis of Organic Contaminants in Hydrogen Peroxide

Volatile organic contaminants in hydrogen peroxide can be analyzed by combustion gas chromatography [827].

Typical contaminants found in Propulse™ rocket-grade HTP are illustrated in Figure 54 from [100].

Figure 54: Typical contaminants found in Propulse™. (From [100], with permission granted by Evonik Operations GmbH.)

The total carbon content in hydrogen peroxide can be analyzed by using a Multi N/C 2100 total C/N analyzer [828]. This method exhibited good linearity, the relative standard deviation was less than 5%, the standard recovery was from 99 to 107%, and the detection limit was as low as 194.2 µg/L.

4.17 Procurement Specifications for Hydrogen Peroxide

Procurement specifications for hydrogen peroxide for military and space propulsion applications have evolved over the years. The most commonly used specifications are the military specifications.

The first military specifications issued covered 70 and 90% HTP intended for use in torpedoes [829]. It required much higher stabilizer levels than the later issued MIL-P-16005. It required the simultaneous use of all three stabilizers for 90% HTP: tin, 4 mg/L, added as sodium stannate $\text{Na}_2\text{SnO}_3 \cdot 3\text{H}_2\text{O}$, 4 mg/L phosphate added as disodium hydrogen phosphate dodecahydrate $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$, 20 mg/L nitrate added as sodium nitrate NaNO_3 and supplemented by nitric acid for pH adjustment. This stabilized HTP was called *E-stabilized hydrogen peroxide*. The impurity limits established for torpedo-grade hydrogen peroxide were based on the stabilization requirements for maximum storability with respect to torpedo use; thus, very high concentrations of the phosphates, tin, and nitrate ions were required. In the establishment of limits for propellant-grade hydrogen peroxide, minimum stabilization requirements had to be met, but concentrations of stabilizers that cause catalyst poisoning were strictly controlled and kept as low as necessary. Phosphate, which acts as a stabilizer by complexing the heavy metal ions that promote H_2O_2 decomposition, is a severe catalyst poison; thus, its content in propellant-grade H_2O_2 is limited. Tin (as stannous chloride) is added to the peroxide as a stabilizer to offset the effects of residual phosphate; therefore, a minimum limit was established for tin. The tin content in H_2O_2 will gradually decline during storage due to colloid agglomeration and suspended particle settling from the solution. The chloride and sulfate ion concentrations are limited because they cause container corrosion (through solution of aluminum). Nitrate has been found to inhibit the effects of chloride and sulfate, and a lower level has been established for this ion to inhibit container corrosion.

MIL-P-16005 Rev. E was released in 1968 and canceled in 1988. MIL-P-16005 Rev. E was intended to control 90 and 98% H_2O_2 rocket oxidizer and monopropellant and was used in programs such as Redstone, X-15, and Scout. The cancellation coincided with termination of the Scout satellite launch vehicle in the US (the Scout derivative rocket was used in Italy a few years longer than in the US). At that time, hydrogen peroxide covered by the MIL-SPEC was made by three different methods: electrolytic, anthraquinone, and isopropyl alcohol methods. As of 2000, only the anthraquinone process is still in use in the US. That affected the types of contaminants one had to look for. MIL-P-16005 Rev. F was issued in 2003 [830, 831].

Table 52 gives a summary of the purity and assay requirements established by military specifications for several types and grades of HTP. There are two different grades for HTP: Grade ES – **extra** stabilizers, which contains higher concentrations of stabilizers, and Grade HP – **high** purity which conforms with stricter limits on types and concentrations of stabilizers and metals.

Table 52: Military Specification MIL-PRF-16005E requirements for hydrogen peroxide assay and purity.

Properties	Limits				
	Type 70	Type 85	Type 90	Type 98	
	Grade ES	Grade ES	Grade ES	Grade HP	Grade HP
Hydrogen peroxide assay (percent by weight)	71.0–73.0	85.0–87.0	90.0–91.5	90.0–91.5	98.0–99.0
Anions					
Chloride (Cl ⁻) mg/kg	0.8 max	0.2 max	2 max	0.5 max	0.5 max
Nitrate (NO ₃ ⁻) mg/kg*	3.9 max	5.0 max	7.5 max	5.0 max	5.0 max
Phosphate (PO ₄ ³⁻) mg/kg	0.2 max	0.2 max	0.5 max	0.2 max	0.2 max
Sulfate (SO ₄ ²⁻) mg/kg	2.3 max	0.5 max	5 max	0.5 max	0.5 max
Ammonium (NH ₄ ⁺) mg/kg	2.3 max	3.0 max	3.0 max	3.0 max	3.0 max
Stability (24 h/100 °C) % loss of active oxygen	2 max	2 max	2 max	2 max	2 max
Evaporation residue mg/kg	15 max	10 max	—	20 max	20 max
Total carbon, mg/L	200 max	40 max	105 max	40 max	40 max
Metals					
Aluminum (Al) mg/L	0.2 max	0.2 max	1.0 max	0.35 max	0.35 max
Tin (Sn) mg/L	0.8–3.1	1.0–4.0	0.7–7.0	1.0–4.0	1.0–4.0
Chromium (Cr) mg/L	0.11 max	0.03 max	—	0.03 max	0.03 max
Lead (Pb) mg/L	0.04 max	0.03 max	—	0.03 max	0.03 max
Manganese (Mn) mg/L	0.04 max	0.03 max	—	0.03 max	0.03 max
Iron (Fe) mg/L	0.11 max	0.03 max	—	0.03 max	0.03 max
Copper (Cu) mg/L	0.04 max	0.03 max	—	0.03 max	0.03 max
Nickel (Ni) mg/L	0.04 max	0.03 max	—	0.03 max	0.03 max
Antimony (Sb) mg/L	—	—	—	0.03 max	0.03 max
Arsenic (As) mg/L	—	—	—	0.03 max	0.03 max

Titanium (Ti) mg/L	—	—	—	0.03 max	0.03 max

*A high-purity grade shall be available with a minimum level of 2.0 mg/kg nitrates when requested

MIL-PRF-16005D in its 1965 issue specified only two grades of HTP, and the purity requirements for the Type II (98–99% H₂O₂) were essentially the same as for the Type I (90–91% H₂O₂). Total carbon is the same as **total organic carbon**, often abbreviated as TOC. Evaporation residue is the same as non-volatile residue (NVR).

As of 2002, there were insufficient data to support the establishment of tolerable contaminant levels for 98% HTP. In an effort to establish tolerable levels of contaminants, pure 98% HTP was doped with known amounts of contaminants (one at a time) and tested in two small thrusters with two different catalysts for run times up to cumulative 3000 s [832]. The results of the thruster tests with pure and adulterated HTP propellants are shown in *Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide Monopropellants”. The recommended 98% HTP specification is shown in Table 53 in comparison to the standard MIL-SPEC.

Table 53: Recommended 98% HTP specification in comparison to MIL-SPEC.

	Recommended 98% HTP specification	MIL-P-16005E
Assay, mass-%	98–99%	98–99%
Aluminum (Al^{3+})	0.35 mg/L max	0.5 mg/L max
Chloride (Cl^-)	0.5 mg/L max	1.0 mg/L max
Ammonium (NH_4^+)	3.0 mg/L max	3.0 mg/L max
Nitrate (NO_3^-)	3–5 mg/L	3–5 mg/L
Phosphate (PO_4^{3-})	0.2 mg/L max	0.2 mg/L max
Sulfate (SO_4^{2-})	0.5 mg/L max	3.0 mg/L max
Tin (Sn)	1–4 mg/L	1–4 mg/L
Total organic carbon	40 mg/L max	200 mg/L max
Non-volatile residue	20 mg/L max	20 mg/L max
Stability	2.0% max AO	2.0% max of AO
Ni	0.03 mg/L max	N/A
Cr	0.03 mg/L max	N/A
Fe	0.05 mg/L max	N/A
Cu	0.03 mg/L max	N/A
Mn	0.03 mg/L max	N/A

Table 54 is a comparison of supplier’s certificates with the expired MIL-SPEC requirements.

As of 2001, none of the MIL-SPECs were still in effect, and it was recommended that the HTP industry and HTP should form a working group and agree on a new specification. In addition, a new specification would be needed for 98% H_2O_2 , which was not yet covered by any of the expired specifications. The expired MIL-P-16005E could be used as “model” for the new specification [833].

If the hydrogen peroxide renaissance had survived, eventually the USAF Directorate of Aerospace Fuels in San Antonio, TX would have had to stock up on HTP to supply government and contractor users with this propellant [834]. They offered a draft of a new procurement specification that covered 70, 85, and 90% HTP (but not yet the 98% grade).

Table 54: Comparison of supplier's certificates with the expired MIL-SPEC requirements.

Hydrogen peroxide, mass-%	Type I MIL-P-16005E	FMC	Degussa "Propulse"
Property, ppm max	90.0–91.0	90.0–91.0	90.0±0.5
Aluminum	0.35	0.2	1.0
Chloride	0.7	0.2	2.0
Ammonium	2.2	0.2	1.4
Sulfate	2.2	0.2	5.0
Nitrate	3.6 max, 2.2 min	3.5 max, 2.2 min	7.2
Phosphate	0.15	0.15	0.5
Tin	2.9 max, 0.7 min	3.0 max, 1.0 min	5.0 max, 2.0 min
Carbon	144	50	72

In Russia, organic impurities contents in the 35–40% product that goes into concentrators are limited by Russian specifications to 0.55–0.7 mass-%, containing 0.2–0.3 g/dm³ of isopropanol, 6–8 g/dm³ of acetone and 6–8 g/dm³ acetic acid [107–109].

5 Materials of Construction for Hydrogen Peroxide

The literature on materials of construction for hydrogen peroxide can be chronologically subdivided in two major groups: one before 1960 and one after 1995, with a wide gap of inactivity in between. The older materials compatibility data have the disadvantage that they were obtained using obsolete test methods, or that many of the commercial materials (in particular polymeric materials and lubricants) tested are no longer available or have been reformulated. The other problem is that many recently developed materials (metallic and polymeric) have not yet been tested for compatibility with HTP.

In discussing materials of construction and declaring them compatible or incompatible with hydrogen peroxide (or any other rocket propellant), one must differentiate between the effect of leached materials on the stability of the propellant or the corrosive effect of the propellant on the material, eventually causing it to lose its structural integrity. In the worst case, both can occur at the same time. Both phenomena are generally lumped together under the term "compatibility", and either one can cause a material to be branded as "incompatible" and rejected for further use with H₂O₂.

A good collection of compatibility data is in an old, historical Becco company bulletin that is no longer available [835], but its contents have been absorbed and reprinted later in other hydrogen peroxide handbooks [836]. Third-hand sources are usually less reliable and often depend on undocumented information, some of it copied several times. Each time such information gets copied, it loses some of its

authenticity and accuracy. The current book at hand is only a third-hand source but tries to evaluate the reliability of the information provided. Some of the information is now obsolete and has been superseded by more recent data.

Another good and very comprehensive source of physical properties and materials compatibility data is the *Hydrogen Peroxide Handbook* compiled by Rocketdyne under contract to the AFRL [246]. It contains reprinted (and untested – no warranty implied for accuracy) materials compatibility data taken from HTP manufacturers' product bulletins that are no longer available directly from the producers.

The first edition of our book on rocket propellants in 1968 contained a lengthy list of materials recommended by Becco, which was a major manufacturer of HTP at that time. The materials were categorized into four classifications of suitability, and this categorization is still used nowadays:

1. Suitable for service under all conditions, also temperatures up to 373 K (100 °C) and long storage times.
2. Suitable for repeated exposure and short-term use, such as in valves, plumbing, pumps, and run tanks in stationary rocket test sites. These materials should not be allowed into contact with HTP for longer than 4 h at 343 K (70 °C) or 1 week at 294 K (21 °C).
3. Only suitable for very short contact times with liquid or vapor H_2O_2 , such as in combustion chambers or propellant ducts in expendable launch vehicles.
4. Not suitable for use under any circumstances. These materials either catalyze the decomposition of H_2O_2 or lose their structural integrity once contacted by H_2O_2 . Other modes of incompatibility lead to the formation of explosive mixtures, such as those formed by H_2O_2 and hydrocarbon oils used as lubricants.

5.1 Other Summaries of Information on Compatibility of Materials of Construction with Hydrogen Peroxide

Hydrogen peroxide was evaluated as an oxidizer for an advanced propellant staged combustion feasibility program, and its physical, chemical, and handling properties were compiled in a handy summary report, although most of the data were taken from the book by Schumb and various manufacturers' bulletins [183]. It is just that these product bulletins are no longer available because some of the HTP manufacturers are no longer in business. However, the Anderson summary is still available on the Internet, and it is a valuable resource, although the quality of reproduction is poor, and some of the text is hard to read; see also [24, 837].

5.2 Test Methods for Evaluation of Materials of Construction for Hydrogen Peroxide

There are several test methods that are specifically suitable for the testing of various materials of construction in contact with hydrogen peroxide, simulating conditions under which the materials might be used in a rocket. This list is essentially a replica of methods already described in Section 4.7 for the evaluation of the thermal and storage stability of hydrogen peroxide by itself in containers known to be compatible.

Material test methods from the good old 1960s were used as a starting point in evaluating materials compatible with HTP for use in a new generation of space launch vehicles at the beginning of the twenty-first century. These established test methods were modified to incorporate modern analytical laboratory equipment and to test a wide range of materials incorporating the new polymer and composite materials that have become available since the 1960s [838]. Testing was accomplished in three stages, from quick screening to detailed analytical tests. A long-term storage test of a subscale tank lasted only 7 months before being stopped due to a polar boss material breakdown. Chemical examination of the hydrogen peroxide and residue left on the polar boss surface quite clearly identified a material corrosion problem.

The test procedure used at Angeles Crest Engineering consisted of immersing material specimens having a surface area of 30 to 60 cm² in about 90 mL of concentrated hydrogen peroxide contained in a Pyrex[®] glass vessel of about 125 mL capacity [839]. Several such vessels were placed in air convection chambers with precise temperature control for 200 h. Typically, nine to twelve vessels were placed in each convection chamber. Three convection chambers were available so that tests could be performed simultaneously at three different temperatures of 316.4, 325.3, or 335.3 K (43.3, 52.2, or 62.2°C). The gas evolved was collected in water-filled inverted graduated cylinders, one for each test sample. The published results are useless because the concentration of hydrogen peroxide and the identity of the materials tested were not revealed.

A crude method of testing crucible-shaped metal samples for compatibility with HTP was described in [840] (although 140 day is **not** a “**long-term** storage test demonstration”!). Crucibles of Al-3003, zirconium, and tantalum were filled with HTP, placed in a glass beaker at room temperature, and the gas evolved was collected by inflating (and periodically venting) the attached rubber balloons. Zirconium had good compatibility, Al-3003 was the worst, with tantalum in-between.

5.3 Metallic Materials of Construction for Hydrogen Peroxide

A summary of materials of construction and their classification into the above four-class categories is given in Table 55, along with some observations on changes of the material as the result of H₂O₂ exposure.

Table 55: Materials compatibility with 90% H₂O₂, Part I Metals.

Although aluminum by itself and many stainless steels by themselves are compatible with H_2O_2 , a combination of these two metals will cause galvanic corrosion, and the aluminum becomes coated with a gel of aluminum hydroxide.

The most common metals for hydrogen peroxide tankage and storage installations are aluminum alloys. The following sections provide detailed information on individual materials intended to supplement the overly simplified summary given in Table 55.

In selecting aluminum alloys for H_2O_2 service, it is important to select alloys with low copper content. Copper is often added to aluminum alloys to increase tensile strength. One can find a direct correlation between the amount of allowed copper in the alloys and the rate of gas formation when H_2O_2 is in contact with these alloys.

Metal coupons were immersed in HTP at room temperature and elevated temperature, and the weight change of the coupons and the loss of H_2O_2 content of the liquid was measured for varying lengths of time [365]. The few satisfactory materials in which concentrated peroxide may be handled or stored are (in the decreasing order of preference) Pyrex[®] glass, aluminum (99.6% pure or better), aluminum-magnesium alloys, pure tin, pure tantalum, pure cadmium, and stainless steel. All of these surfaces must be conditioned (passivated) before use with HTP.

Several hundred metals and other materials of construction were evaluated in contact with 90% HTP in a multi-year effort at Shell Development Company [166]. The surface activities of fresh and passivated metals were compared to find the most effective passivation methods. The aluminum alloys tested were Al-1260, Al-1100, Al-2219, Al-5052, Al-6061, Al-7039, and Al-7072. One of the test methods was to measure the rate of oxygen evolution of the metal coupons kept in 90% HTP (with different stannate stabilizer levels) at 373 K (100 °C). The activity of CRES-304 and CRES-347 decreased with the duration of HTP immersion but was still several orders of magnitude worse than what can be achieved with aluminum alloys. In addition to passivated metal samples, some tin-electroplated metal samples were also tested. It would be desirable to revisit some of these reports and put the data in a user-friendly graphical format, also in comparison to other materials compatibility studies conducted at other organizations during the same time or in the interim.

While compatibility with HTP has been worked on for 80 years, newer materials were not yet considered in the early years. To fill this gap, various metals, polymers, and composites were examined by microcalorimetry [841]. At first, methods were developed for the production of HTP on site [842], and then compatibility test methods selected included accelerated aging by heating, coupled with assay of concentration and stabilizer loss, observation of reactivity by means of isothermal microcalorimetry, and evaluation of changes to the materials by short-beam shear testing and by photoacoustic-Fourier transform infrared spectroscopy. Material coupons (Al-6061, CRES-304, 17-4PH, CRES-330C) were immersed in 4 mL of 90% H_2O_2 and heated to 338 K (65 °C) for 6 h. The mass loss and concentration of the surviving H_2O_2 gave a measure of compatibility. The reactivity decreased in the order Al-6061, CRES-304, 17-4PH, and CRES-330C. The HTP in contact with CRES-330C decomposed totally.

Welding of stainless-steel leaves behind an oxide and slag layer that may be less compatible with H_2O_2 than the clean, passivated parent metal. Many metal oxides such as those found in weld slag are perfect catalysts for decomposition of H_2O_2 , and the presence of metal oxides in weldments is a problem for the manufacturing of HTP equipment. The HTP compatibility of welded versus unwelded stainless steel was studied using microcalorimetry [843, 844]. An isothermal microcalorimeter (Model 4400, Water Bath Model 7238, Calorimetry Sciences Corp, Provo, UT) was used to obtain heat flow measurements at 333 K (60 °C). Welded specimens of CRES-304L and CRES-316 were significantly less compatible than their unwelded counterparts, with the CRES-304L falling beyond the upper limit of Class 2 materials. In the heat-affected zone of the weld, the ratio of chromium to iron increased from 0.28 to 0.44 in CRES-304L and from 0.26 to 0.79 in CRES-316. Chromium oxide is a bad actor for H_2O_2 compatibility.

Using the same microcalorimetry method, various candidate metals to be used in the injectors of HTP rocket engines were tested [845, 846]. Inconel-625 and Ni-200 had very poor compatibility and were immediately excluded from further evaluation. A-286 had marginal compatibility. CRES-347 had acceptable compatibility considering the short duration it would be in the wetted state.

5.3.1 Contaminant Effects on Corrosivity of Hydrogen Peroxide

5.3.1.1 Corrosion Inhibitors

Chlorine impurities introduced into the hydrogen peroxide during the manufacturing process from water or are introduced by water used in less carefully controlled handling operations, can make hydrogen peroxide significantly more corrosive. To counteract this corrosive nature, nitrates were sometimes added to act as a corrosion inhibitor. Advances in the manufacturing technology of hydrogen peroxide may have reduced the chlorine level, thereby reducing the corrosive behavior of hydrogen peroxide. It is possible that modern propellant-grade hydrogen peroxide may no longer have the corrosive effects on 6061 aluminum that it had in the past.

The chloride content of H_2O_2 has a pronounced effect on the rate of corrosion of all alloys in H_2O_2 . It has been suggested that addition of ammonium nitrate as a corrosion inhibitor can retard the rate of corrosion caused by chloride contamination. The maximum amount of chloride in HP grade HTP allowed by MIL-PRF-16005E is 0.5 ppm.

5.3.2 Aluminum and Aluminum Alloys

One of the most frequently used aluminum alloys for H_2O_2 service is Al-1060. It is essentially soft, pure, unalloyed aluminum with 99.6% Al. It has a negligible rate of corrosion, and the loss of H_2O_2 concentration during storage is minimal. In those few cases where corrosion (pitting corrosion) was observed with this alloy, it was usually traced contaminants introduced during machining or welding.

In long-term storage tests, 90.5% H_2O_2 was stored in 114-L Al-1060 drums for over 3 years. The average rate of loss of H_2O_2 concentration was only 1% absolute. In large, spherical storage tanks holding 95000L, the loss of H_2O_2 concentration during 12 months storage could not be detected. If HTP has been shipped in drums and is not intended to be used immediately, it may be advantageous to transfer it into a single, large on-site tank. The transport drums are not intended for long-term storage of the material. Different Al alloys (Al-1060, Al-5052, Al-5652, and Al-5254) were tested as material of construction for 55-gallon drums. Based on storage tests at customer installations extended to 3 years, none of the samples lost more than 2% H_2O_2 per year when the drums were returned to the manufacturer (Becco) for examination.

Al-1060 causes the least amount of H_2O_2 decomposition, but it is a very soft alloy and does not have the mechanical strength required for some applications. If the system is designed for high-pressure operation, the wall thickness of tubing and tanks must be increased accordingly. Materials like Al-5254 or Al-5652 have better strength and may be used for tank cars that have to withstand higher mechanical loads (road vibrations) than stationary tanks. Although HTP is normally not stored in these tank cars, storage times of up to 3.5 months have been monitored without complications.

The mechanical strength of aluminum alloys also depends on the annealing (tempering) cycle the material has undergone since it was extruded, rolled, or welded.

Aluminum 6061-T6 is the most frequently used aluminum alloy for many structural elements. Although it has good mechanical properties, it does not hold up well when the service requires alternating exposure to H_2O_2 liquid, H_2O_2 vapor, and water. It has been recommended to render it more compatible by anodizing it in sulfuric acid.

Al-2014, Al-2017, and Al-2024 are stronger alloys than Al-6061 but have been downgraded to a Class 3 compatibility category because they accelerate H_2O_2 decomposition during storage. Their compatibility could not be improved by anodizing.

For many years, pump and valve casings have been made from Al-43 and Al-356, although these are categorized in Group 3 and are not very compatible with H_2O_2 . It is possible to manufacture Al-356 with a controlled and reduced copper content, earning it the designation Al-356B and classification in Group 1.

Comparing the rate of unstabilized HTP (87.2% H_2O_2) decomposition in contact with aluminum of five different grades of purity (increasing purity from 99.39, 99.49, 99.61, 99.70 to 99.80%) but decreasing iron content (0.51, 0.43, 0.26, 0.23, 0.14% Fe) showed a direct inverse correlation of the rate of HTP decomposition with the iron content in the aluminum [365].

The mechanism of corrosion of Al alloys in H_2O_2 (in the absence of chloride) can be studied by measuring electrochemical potentials of aluminum coupons against reference electrodes. There are two different rates of corrosion, one related to the rate of forming a protective film of aluminum oxide and the other related to the rate of aluminum oxide film dissolution or spalling [847]. A distinction can be made between the electrochemical corrosion of metallic aluminum, in which aluminum oxide is formed, and the chemical solution of the aluminum oxide, eventually leading to the interac-

tion of aluminum ions with the stannic acid stabilizer. The electrochemical reaction is facilitated by chloride ions and retarded by nitrate ions, whilst the chemical solution is enhanced by hydrogen ions and the presence of stannic acid sol. Only the chemical reaction affects the stability of the stannic acid stabilizer.

Nine wrought and three cast aluminum alloys were exposed to commercial 90% H_2O_2 as manufactured and 90% H_2O_2 with 3 g/L chloride ion and 4 g/L nitrate ion added [848]. Testing included wrought alloys 1100-H14, 5254-H14, 1260-H14, 6363-T5, 3003-T14, 6061-T6, 5652-H34, 5086-H34, and 1060-H14, and three cast alloys Al-356, Al-43, and Al-B-214. Most of the exposures were of 6 month's duration. Some of the specimens had to be removed prematurely due to severe corrosion or rapid deterioration of the hydrogen peroxide. Samples were characterized by tensile strength, stress corrosion, metallographic examination, and chemical analyses of the hydrogen peroxide in order to determine its loss of active oxygen. The presence of chloride ion was found to accelerate corrosion greatly in all of the alloys. Wrought alloys 5254 and 3003 were found to be the most compatible, and B-214 was the best cast alloy.

Currently, aluminum alloy 5254 is the state-of-the-art material for HP storage, but its yield strength is very low (420 ksi), and it may not be suitable for the development of light-weight propellant tanks for Hyper-X vehicles. A new high strength and HTP propellant compatible aluminum alloy has been developed for NASA Hyper-X vehicle propellant tanks and structures [849]. The tensile strength of the new alloy is more than three times better than that of the conventional Al-5254-H112 alloy, while it still maintains an HTP compatibility similar to that of Al-5254 (i.e., Class 1 category). The alloy development strategy is to add scandium, zirconium, and other transition metals with unique electrochemical properties, which will not act as catalysts and will not decompose liquid HP. Test coupons were machined from sheet metals for HTP compatibility testing in a microcalorimeter, long-term immersion testing and mechanical properties testing [850]. The Appendix to this report contains a description of the standard test methods to determine materials compatibility (expressed as AOL) and HTP stability.

It was attempted to reduce the deactivation of stannate stabilizer by aluminum uptake into HTP from aluminum storage tanks by plating the aluminum with tin [166, 174]. Unfortunately, aluminum is difficult to electroplate with any metal, and the only metals tin can be easily electroplated onto are those that are very active in H_2O_2 decomposition. Those more active metals would have to be completely coated with tin without any pinholes.

The electrochemical behavior of aluminum in concentrated hydrogen peroxide has been studied by measuring the electrode potentials and the "corrodance", i.e., the inverse of polarization resistance [851]. Electrode potentials depended on the presence of chloride and nitrate ions. "Corrodance" determination is a convenient method for the rapid measurement of the very low corrosion rate of aluminum in hydrogen peroxide.

Al-6061-T6 has the desirable strength but is incompatible with HTP. In storage tests with 85% HTP for 10–20 weeks in tanks made from sections of 7.5-cm (3-in.) diameter pipe, increased decomposition was observed not only while the HTP was in contact with the metal but also homogeneous decomposition due to leached metal ions after the propellant was unloaded [852]. The compatibility could be improved somewhat by anodizing the aluminum. The off-loaded propellant was analyzed for leached metals and fewer metals were leached from the anodized aluminum Al-6061-T6.

Cleaning and Passivation of Aluminum Tanks

The Hydrogen Peroxide Handbook by Constantine and Cain contains a good summary of the cleaning and passivation methods used for metal tanks prior to their first use with HTP [853]. Several of the following sections on recommended passivating methods have been excerpted from that source:

Non-anodized aluminum and aluminum alloy parts may be descaled by immersion in a 1% HF-10% HNO₃ solution for 30 s to 5 min at 319 K (115°) maximum. Immediately following the cleaning (or descaling) operation, the metal parts should be subjected to the “basic passivation” step.

Aluminum and aluminum alloy materials are usually passivated with a solution of 45% HNO₃ at room temperature for a period of 1 h; however, FMC recommends the use of 35% HNO₃ as the passivation acid. The materials should be rinsed and flushed with water to remove all traces of nitric acid, and unless immediately conditioned with the propellant, the materials should be drained and dried by purging with dry, filtered, hydrocarbon-free nitrogen or air, or dried in a clean oven at 333 to 339 K (140 to 150 °F). Machined aluminum bar stock parts do not normally require descaling or passivating processes and can be prepared for service by degreasing and thoroughly rinsing. Welded, cast, or corroded parts will require descaling, cleaning, and passivating. Anodized aluminum parts will not be descaled or passivated and should be prepared for service by degreasing and thorough rinsing.

5.3.3 Stainless Steel Alloys

Stainless steels of the 300-series are suitable only for short term use (Group 2). Cast-iron steels are not recommended (Group 3). CRES-303 has caused problems in the past and is generally avoided.

The compatibility of 98% H₂O₂ with four nickel alloys (Ni-200, INCO-625, CRES-347, and A-286) was tested and found to be much better than that of 90% H₂O₂ under the same test conditions [402]. This observation was explained by the hypothesis that an inert protective metal oxide layer formed on the surface of nickel alloys in the presence of 98% H₂O₂. No such oxide layer formed when similar coupons were immersed in 90% H₂O₂ solution. For compatibility tests, material coupons were immersed in H₂O₂ solution at 339 K (66 °C) for 1 week. The ratio of coupon surface to H₂O₂ volume

was about 0.33 in.^{-1} . The off-loaded HTP was analyzed for leached metals by inductively coupled plasma (ICP) emission spectrometry. For stability tests, 50 mL of H_2O_2 solution was maintained at 373 K (100 °C) for 24 h. The reserve stability of stabilized H_2O_2 solutions towards decomposition was challenged by adding controlled amounts of five metal cations in the form of their nitrates that might be leached from container metals. With 98% H_2O_2 , the order of decreasing catalytic activity of these cations is $\text{Mn}^{2+} > \text{Cu}^{2+} > \text{Fe}^{3+} > \text{Cr}^{3+} > \text{Ni}^{2+}$ (Figure 55).

Figure 55: Stability of 98% HTP as a function of contaminant dopant concentration. (Reproduced and modified from [402].)

Trends in stability for doped and undoped H_2O_2 solutions were quantified for the concentration range of 10–98% H_2O_2 . A study of the role of pH on stability showed that a broad maximum in stability existed over a pH range of 0 to -2.5 (Figure 44). Stannate at 2.7 ppm Sn provided a reserve stability (with no change in measured stability) up to 190 ppb of added Fe.

The thermal decomposition rate of 98% HTP in contact with candidate materials of construction was tested by measuring gas evolution by volumetry and heat evolution by isothermal microcalorimetry (IMC). Materials were analyzed for compatibility with HTP, including a study of the effect welding on stainless steel elemental composition and its relation to HTP decomposition [854]. Using an isothermal microcalorimeter it was found that two of the metal samples were not compatible with 98% HTP and, therefore, they are not recommended for use as structural materials. Composition changes in stainless steel CRES 304L and CRES 316L due to welding were apparent from an X-ray fluorescence (XRF) analysis. A correlation between an enhancement in Cr and Cu in the weld bead and an increase in the HTP decomposition rate in the IMC

was supported by the data obtained by XRF. This report is useless because the metals M1, M2, M3, and M4 were not identified.

Gas evolution rates of stainless steel (15–5 PH, CRES 304L, AISI 430) cylinders immersed in 87.7% H_2O_2 in 25-mL Pyrex[®] flasks were measured at four different temperatures (278, 293, 305, 323 K = 5, 20, 35, 50 °C) in four parallel tests along with a control flask that contained only HTP and no metal sample [855]. The surface: volume ratio was 1.1 cm^{-1} . The gas evolution rates plotted on a semilogarithmic scale versus temperature showed a linear relationship.

Water and hydrogen peroxide are very poor lubricants for metal pieces in sliding contact with each other as in the bearings of pumps and flowmeters. Pin-on-disc tests to investigate the tribological behavior of an AlCoCrFeNiCu alloy under rotating friction conditions with 90% H_2O_2 solution in comparison to lubricant oil demonstrated that the AlCoCrFeNiCu alloy was well lubricated with 90% H_2O_2 or lubricant oil, both significantly improving friction and wear-resistance properties [856].

The rate of friction wear of an AlCoCrFeNiTi0.5 alloy in high-concentration hydrogen peroxide solution depends on the crystalline microstructure formed during the annealing process, which leads to an increase of the hardness of this alloy [857]. Friction curves of 1Cr18Ni9Ti and AlCoCrFeNiTi0.5 stainless steels in contact with SiC or ZrO_2 ceramics were measured.

Stainless steel is widely used in strongly oxidizing hydrogen peroxide environments. It is important to study its wear behavior and failure mode under conditions of high friction. The tribological properties and oxidation of 304 stainless steel were investigated using an MMW-1 tribo-tester with a three-electrode setup in H_2O_2 solutions with different concentrations [858]. Corrosion current densities (CCDs), coefficients of frictions (COFs), wear mass losses, wear surface topographies, and metal oxide films were analyzed and compared. The results showed that the wear process and oxidation processes interacted with each other. Increasing the H_2O_2 concentration or the oxidation time was useful to form a layer of integrated, homogeneous, compact, and thick metal oxide film. The dense metal oxide films with higher mechanical strengths improved the wear process and also reduced the oxidation reaction. The wear process removed the protective metal oxide films to increase the oxidation reaction.

Cleaning and Passivation of Stainless Steel Tanks

In preparation for passivation, stainless-steel parts should be etched for a minimum period, and not longer than 60 min, at room temperature, 289 to 300 K (60 to 80 °F), with a mixture of 3% technical-grade hydrofluoric acid and 10% technical-grade nitric acid in water. Immediately following the cleaning (or descaling) operation, the metal parts should be subjected to the “basic passivation” step, which consists of immersing stainless-steel parts in a solution of 45% HNO_3 at 289 to 300 K (60 to 80 °F) for a minimum period of 30 min. FMC recommended the use of 70% HNO_3 for a period of 4 to 5 h as the stainless-steel passivation step [859]. The parts should then be rinsed and flushed thoroughly with deionized or distilled water to remove all traces of the

passivating solution. Unless the part is immediately placed in the propellant-conditioning solution, it should be drained and dried by purging with dry, filtered, hydrocarbon-free nitrogen or air, or dried in a dust-free oven at 333 to 339 K (140 to 150 °F). The part should then be protected from recontamination by sealing in a sealed clean plastic bag.

The nitric acid passivation solution should be used for AISI 300 and 400 series stainless steels. The protective film resulting from this passivation process will not normally be visible, but the surfaces will be uniform in appearance, free from scaling, corrosion, pitting, and contaminants. Normal discoloration from welding will be permitted, provided that no scale or rust is associated with the discoloration. Some organizations recommend electropolishing of stainless-steel parts (except for AN 355) by the best available commercial practice as an alternate method for stainless-steel passivation. Following electropolishing, the material should be cleaned with detergent, rinsed thoroughly with deionized or distilled water, and dried in an oven.

When stainless steel is immersed in HTP, an oxide film is formed on the surface of the metal. The rate of formation, composition, and stability of this film were investigated by chemical analysis and electrometric methods. The film consisted mainly of oxides of iron, and at 30 °C it grew to a fairly constant thickness of 3×10^{-6} cm in 3–4 weeks [860]; see also [861].

5.3.4 Cleaning and Passivation Methods for Metal Tanks

The Hydrogen Peroxide Handbook by Constantine and Cain [246] contains a good summary of cleaning and passivation methods used for metal tanks prior to their first use with HTP. The following was excerpted from that source:

All material surfaces that come in contact with propellant-grade hydrogen peroxide must be specially cleaned and treated prior to their use to minimize hydrogen peroxide decomposition and material corrosion. The material surfaces should be subjected to passivation after part fabrication and before component or system assembly.

Basically, items such as valves, pumps, actuators, system piping, etc., cannot be cleaned properly in the assembled state, because the solvent, cleaning solution, residual contamination, etc., may be trapped in inaccessible areas. The cleaning should be conducted immediately before component or system assembly, unless provisions are made for packaging of the passivated part to protect them against recontamination until ready for assembly. After assembly, components, such as valves, should be packaged until they are utilized in the final system assembly. It is also common practice to check all passivated items for gas evolution with propulsion-grade hydrogen peroxide prior to assembly in the system.

The general terminology applied to this process, which is designed to provide an inactive surface and eliminate potential contamination active sites, is *passivation*. The passivation procedure essentially consists of **three primary steps** prior to the material contact with propellant-grade hydrogen peroxide. The initial step is a chemical

and physical cleaning procedure designed to remove oxides, scale, dirt, weld (and heat treat) slag, oil, grease, and other foreign material from the base material. The second step is usually the treatment (“basic passivation”) of the material with an alkaline or acidic solution to form a surface film (probably a complex oxide) on the surface to minimize chemical or catalytic activity between the surface and the propellant. Finally, the material is subjected to propellant conditioning to check the completeness of the chemical treatment and to eliminate, through further oxidation and chemical complexing, all remaining active sites. Normally, propellant conditioning is conducted in 35% H_2O_2 , although many organizations prefer additional propellant conditioning of materials under the same conditions (H_2O_2 concentration and temperature) that will be experienced in actual application of the material.

A comparative evaluation of several passivation or surface preparation techniques was conducted to: (1) determine the effectiveness of selected passivation methods on 321 stainless steel, 6061-T6 aluminum (bare and anodized), and Silastic 9711, (2) determine the influence of cyclic exposure of passivated surfaces to hydrogen peroxide, and (3) investigate the effects of various storage conditions upon passivity of materials used in hydrogen peroxide service [862]. The passivation methods under study were:

- LTV Astronautics Division CVA-10-62a
- North American Aviation, Inc., El Segundo, California, LA 0110-003
- Walter Kidde 520007
- FMC Becco Bulletin 104
- McDonnell A/C 13002
- LTV Astronautics Division 308 – 20-3
- LTV Astronautics Division CVA-10-64a

The company-internal documents where these passivation methods are described in detail are unfortunately no longer available. LTV Astronautics Division developed several passivation methods during the development of the Scout satellite launcher. The preferred passivation method for 321 stainless steel was found to be CVA 10-62a with post-treatment with 35% commercial hydrogen peroxide. For 6061-T6 aluminum (bare and anodized), the best passivation technique was according to North American Aviation Specification LA-0110-003. The ease in passivation of all materials was found to improve with each subsequent exposure to concentrated hydrogen peroxide. Environmental exposure tests revealed that 321 stainless steel can be stored best in clean air with relative humidities up to 1.00%. Anodized 6061-T6 aluminum remains more passive in a dry nitrogen atmosphere.

5.3.5 Effect of the Surface Finish of Metal Tanks

The effect of the surface finish on materials compatibility with H_2O_2 was studied by comparing five different surface finishes applied to 304 stainless steel and aluminum

alloy 6061-T6 (both bare and anodized) in contact with 90% H_2O_2 to determine the influence of the surface finish on the stability of H_2O_2 [863]. The stainless-steel specimens were passivated according to CVA Specification 10-62a with post-treatment in 35% inhibited (0.03% H_3PO_4) hydrogen peroxide. The aluminum specimens were passivated according to North American Specification LA 0110-003. Although inconsistent correlations were obtained between the surface finish and AOL with the 304 stainless steel and the bare Al-6061-T6 specimens, the active oxygen loss resulting from the anodized aluminum in contact with the hydrogen peroxide indicated an increase in AOL values with surface roughness.

5.3.6 Effect of Dissimilar Metals in Contact (Galvanic Corrosion)

Hydrogen peroxide is a good electrolyte, and many metals that occupy different potentials in the order of electronegativity will corrode more rapidly if the metals are in electrically conductive contact with each other as in a galvanic element. The same happens in any rocket propellant that is electrically conductive.

The decomposition rate of 90% H_2O_2 and metals compatibility was measured with the following dissimilar metal couples: 1060 Al + 6061-T6 Al; 6061-T6 Al + 321 stainless steel; 6061-T6 Al + 316L stainless steel; and 321 stainless steel + 316L stainless steel [864]. The active oxygen loss (AOL) and H_2O_2 stability were determined during an exposure of 10 days at 316.5 K (110 °F) and 7 days at 339 K (151 °F). The tests at 316.5 K (110 °F) revealed no significant influence of the dissimilar metals upon the H_2O_2 . However, the 339 K (151 °F) test revealed that the catalytic decomposition of H_2O_2 was greater for the dissimilar metal couples than for either of the single-metal alloys.

5.4 Non-metallic Materials of Construction for Hydrogen Peroxide

Non-metallic materials include organic polymers and inorganic ceramic materials.

5.4.1 Organic Polymeric Materials of Construction for Hydrogen Peroxide

The selection of non-metallic materials for H_2O_2 service is mostly about the selection of organic elastomers to be used as gaskets, valve seats, and flex hoses. More recently, the search has been expanded to include oxidizer-resistant polymers as liners for tanks and composite-overwrapped tanks that would be much lighter than metal tanks for satellites. The selection of elastomers for protective clothing for propellant servicing personnel will be discussed in a separate chapter. The concern here is about the reactivity of H_2O_2 with elastomers, keeping in mind that the combination H_2O_2 /polyethylene is a popular hybrid rocket propellant. One wants this reaction to take place only in the rocket engine, not prematurely in the tank or in the feed system or on the glove of a propellant fueling technician that the propellant has been spilled on!

Many elastomers contain plasticizers. Whereas the parent material may be compatible with H_2O_2 , the plasticizer may not be. It may either be leached into the propellant or it may become oxidized, or both. One can call oneself lucky if it does not spontaneously burst into flames the first time peroxide comes in contact with plasticized polymers.

In ranking four candidate materials for H_2O_2 service, the ranking would be in the sequence Teflon[®], Kel-F[®], polyethylene, and PVC [865].

Teflon TFE fluorocarbon film was inert to 90% hydrogen peroxide for 900 h at 293 K (70 °C) [866]. There was no evidence of chemical attack on the film, nor any change in its physical properties. The mechanism of chemical attack of 90% hydrogen peroxide on polyethylene films between 323 and 343 K (50 and 70 °C) was identified, and found to vary, depending upon the structure of the polyethylene.

Packing for the glands in dynamic seals around valve stems and pump shafts are best made of Teflon[®] or similar perfluorinated elastomers. If the use of Teflon hoses becomes prohibitive for cost reasons, polyethylene-lined hoses can be used for short-term service just as well, but one must keep the flammability hazard in mind.

Table 56 is essentially a continuation of Table 55; it uses the same four-class compatibility rating scale.

PVC elastomers such as those manufactured under the brand names Vinylit or Koroseal are not suitable for H_2O_2 service because chloride may leach from the elastomer into the H_2O_2 liquid, which subsequently becomes quite corrosive toward all aluminum alloys [867, 868].

Silicone rubber is usually considered compatible with HTP, but there are reports where a silicone rubber bladder ignited accidentally [869].

During the development of the X-15 rocket plane RCS system, it was difficult to find materials that were compatible with the propellant because of the corrosive nature of the 90% concentrated hydrogen peroxide [870]. The selection of a suitable material for the expulsion bladder was especially difficult, inasmuch as it had to be compatible with the hydrogen peroxide propellant under long-time exposures at low temperatures and had to withstand repeated flexing without fatigue in order not to rupture under high load conditions. The first expulsion bladders were constructed of Teflon, but later bladders were made of Vicone, a fluorosilicone rubber. Both bladders functioned satisfactorily except for a tendency to rupture along the creases formed after the propellant is fully expelled, and the bladder is compressed around the standpipe. This structural deficiency has resulted in a short and inconsistent bladder life.

O-rings need to have the elasticity to make a good seal and should not cold-flow under pressure. Eight types of O-rings were evaluated by immersion in 90% HTP at 339 K (66 °C) for 1 week [871]. Only one of the eight O-ring materials was acceptable for use with HTP.

O-ring seals of selected elastomeric and compliant materials were evaluated for resistance to 90% HTP in a simulated end-use test at 296 K (23 °C = 73 °F) [872, 873]. The candidate elastomers were placed under compression in closed cells and exposed to

Table 56: Non-metallic materials compatibility with 90% H₂O₂.

Material	Compat- ibility Group	Rate of loss of ac- tive oxygen in H ₂ O ₂ , %/week at 66 °C	Remarks, observations, effects on material under test
Fluoroflex T-TP 1001	1	3.6	None
Fluran B-4100	3	48.3	Bleaching
Hypalon S-2	4	100	Completely destroyed within 1 h
Hypalon V-56-A	4	100	Swelling
Kel-F	1	3.5	None
Kel-F 800	1	4.5	Slight hardening
Kel-F 820	2	9.0	Hardening
Polyethylene	2	1.0	No visible change but may combust
Teflon (white)	1	2.8	None
Carbon-filled Viton A (black)	3	80.6	Bleaching, blistering, swelling
Koroseal-116	3	23	Bleached and hardened
Tygon B-20	3	2.2	Bleached and hardened
Tygon B-63	3	1.7	Bleached and hardened
Vynlite VG 1914	2	1.5	Bleached and hardened
Vynlite VS1310	3	2.3	Turns opaque, blistering
PVC	3		Turns opaque, blistering
Silicone GE 12650	2	48.5	Slight swelling
Silastic 161	3	43.4	Hardened
Silastic 240	2	24.9	None
Silastic 9711	2	7.4	Slight bleaching
BunaN	4		May combust
Butyl rubber	4	100	Coalesced to a shapeless mass
Mylar A	1	5.0	None
Mylar B	1	1.7	None
Neopren	4	100	Autoignites and burns
Nylon	4		Dissolves
Plexiglas	4	100	Softens and dissolves partially, may combust
Polystyrol	2	9.1	No visible changes but not recommended
Thiokol Polysulfide EC-801-LP-2	4	100	Ignites spontaneously and burns

Data source: Becco FMC

the liquid and vapor of liquid rocket fuels and oxidizers for extended periods of time. The rate of propellant loss through the seal and the change in physical properties of the seal materials were determined. In addition, the effect of temperature on elastomer endurance was determined by exposing the O-rings to H₂O₂ at 344 K (160 °F).

Proper materials for hardware components such as check valves, metering valves, and flow lines, were also difficult to select. The original X-15 reaction control system

was constructed entirely of aluminum. It was discovered, however, that the chemical reaction between the aluminum and the hydrogen-peroxide propellant formed hydroxides. Deposits of these substances resulted in “sticky” valves, clogged orifices, a short catalyst-bed life, and other component failures. During the interim, certain components that came into direct contact with the peroxide propellant were then constructed of stainless steel. However, use of the two different metals caused electrolytic galvanic corrosion wherever the metals were joined and came into contact with hydrogen peroxide and, thus, resulted in various component failures and contaminated propellant. The entire system was finally constructed of stainless steel, which eliminated the problems and increased component reliability.

Lubricants for H_2O_2 service cannot be of the conventional hydrocarbon type used for automobile and other lubrication jobs. Even silicone grease is not suitable. Instead, one must use perfluorinated greases such as Fluorolube[®], Kel-F[®], and PerFluoroLube[®]. Hydrocarbon greases form potentially detonable mixtures with HTP, which may even be shock- and friction-sensitive (like what is observed with LOX). A drop weight apparatus was developed to test the shock sensitivity of H_2O_2 /oil mixtures [874, 875]. One particular lubricant was made from perfluorinated C_4 - C_6 trialkylamines mixed with PTFE powder [876].

The selection of materials for service with 98% H_2O_2 requires increased awareness of potential adverse reactions. Generally, the same materials that previously qualified for the less concentrated 90% H_2O_2 can be used. Only in the case of organic elastomers is the destructive power of 98% H_2O_2 stronger than that of 90% H_2O_2 .

Table 57 gives a comparison of the materials compatibility (both metallic and non-metallic materials) and of their behavior toward 90 and 98% H_2O_2 at 303 and 339 K (30 and 66 °C).

A lot of work has been devoted to identifying the best materials of construction for H_2O_2 systems to minimize the rate of pressure buildup during storage and to eliminate the need for having to vent the tanks periodically to release overpressure. A study of the influence of materials of construction on the rate of the decomposition of very pure H_2O_2 showed that it is essentially impossible to eliminate the effect of the container wall. The decomposition of 90 and 98% H_2O_2 proceeded with measurable speed even in Teflon containers. It can be slowed down by passivating the surface before usage and by adding stabilizers, but it never goes down to zero. Unlike other chemical equilibria, the decomposition cannot be retarded or even reversed by increasing the storage pressure. It has only been attempted to minimize the adverse effect of oxygen overpressure buildup by adding an oxygen scavenger to the vapor space.

Teflon TFE fluorocarbon film was inert to 90% hydrogen peroxide for 900 h at 343 K (70 °C) [877]. There was no evidence of chemical attack on the film, nor of any change in its physical properties. The chemical attack of 90% hydrogen peroxide on polyethylene films between 323 and 343 K (50 and 70 °C) was found to vary depending upon the polymer structure of the polyethylene.

Table 57: Effect of materials of construction on storage stability of 90 and 98% H₂O₂ at slightly elevated temperatures.

Loss of active oxygen, %/week

Data source: [239]

Attenuated total reflectance measurements were made on a perfluorosulfonic acid ion exchange membrane exposed to 90% hydrogen peroxide at 343 K (70 °C). A definite attack on the membrane was shown in a 2-h period, indicating that not all perfluoro organic compounds are inert to 90% hydrogen peroxide [299].

Degussa investigated the long-term compatibility of high-strength hydrogen peroxide with various thermopolymers often used in plastic drum fabrication [97]. In the study, 2-mm thick coupons made from high-density polyethylene (HDPE), polypropylene (PP), polyvinyl chloride/urethane (PVC-U), and a fluorinated polymer (PVDF) were directly immersed in 87% HTP for time periods of up to 3 months, at temperatures of 313 and 343 K (40 and 70 °C). Interim sampling was carried out after 14 days, 1 month, and 2 months, in addition to the ultimate 3-month objective. The coupons were then subjected to physical endurance tests including tensile strength, weight loss/gain, elongation, and mechanical hardness. In addition, the HTP was analyzed to detect any loss of activity. The results of these immersion tests are shown in Table 58.

The study concluded that the high-density polyethylene and PVDF thermopolymers did not exhibit any significant changes in mechanical strength or weight and were considered as having a better long-term stability profile than either polypropylene or PVC. There was, however, a slight loss of HTP activity (from 87.1 to 84.2%), but this might not be entirely attributable to the exposure to the thermopolymer. Under the

Data source: [97]

high-temperature conditions (343K), only the fluorinated PVDF material maintained its durability characteristics. It was concluded that PVDF would be the best all-around choice for the transportation of HTP.

Thermotropic liquid crystal polymer (LCP) resins have been shown to be compatible with rocket grade hydrogen peroxide (RGHP) [878]. It was a challenge to effectively form them into useful net shape articles for the containment and transport of RGHP. Due to the high degree of anisotropy and high melt temperature, controlled tests were set up to explore processing parameters and characteristics of thermoplastic processing as applied to these high-strength polymers [879]. Tanks made from four new Ticona Vectra[®] LCP resins, all sharing aromatic copolyester chemistry, were blown including: Vectra[®] A115, LKX1098, LKX1099, and LKX1100. Results with LKX1099 and LKX1098 were favorable from a processing perspective, but these fumed silica filled resins are the most difficult to manufacture.

Since the 1960s high-performance new fluoropolymers have been developed, which had not yet been extensively tested with HTP. PFA and FEP are two polymers showing the chemically resistant characteristics of PTFE but with thermoplastic properties making them easy to manufacture into propellant tanks (composite-overwrapped tanks or soft liners for metal tanks).

Perfluoroalkoxy or PFA is a type of fluoropolymer with properties similar to polytetrafluoroethylene (PTFE). It differs from the PTFE resins in that it is melt-processable using conventional injection molding and screw extrusion techniques. PFA is very

similar in composition to PTFE and FEP. PFA is softer than PTFE and melts at 578 K (305 °C).

Fluorinated ethylene propylene or FEP is a copolymer of hexafluoropropylene and tetrafluoroethylene. It differs from the PTFE resins in that it is melt-processable using conventional injection molding and screw extrusion techniques. FEP is very similar in composition to PTFE and PFA. FEP and PFA both have low friction and non-reactivity but are more easily formable. FEP is softer than PTFE and melts at 533 K (260 °C).

The thermoplastic nature of the two resins reduces the troublesome porosity sometimes associated with PTFE, however, it retains its inert characteristics. Testing of the decomposition rate of HTP on the two polymers was done by measuring the pressure rise in a sealed borosilicate glass system of a coupon of the polymer immersed in HTP at a constant 305 K (32 °C) [880]. The surface of the samples was examined using X-ray photoelectron spectroscopy (XPS) to determine any changes in the surface chemistry of the polymer and to assess the degree of oxidation (if any) that might have occurred on exposure to HTP. XPS spectra showed that there was no discernable change after the exposure to the HTP, and that no or very little oxidation had taken place. The maximum tensile stress, the offset yield stress, and the tensile modulus were measured for the initial samples with no exposure, after 2 months' exposure and, finally, 4 months' exposure. There was no evidence to suggest that the polymers might lose their mechanical properties with long-term exposure (although 4 months is too short a test to make such a statement). Permeability is a difficult parameter to measure, and the numbers shown in Table 59 are just estimates from a 35-day test.

Table 59: H₂O₂ permeation rate of fluoropolymers.

	Gas volume collected cm ³	Permeation rate g cm ⁻² year ⁻¹ mm ⁻¹
FEP	2.14	0.01005
PFA	2.61	0.01225

Note: Sample thickness 0.5 mm

Data source: [880]

Stored HTP was passed through a silver catalyst to see if any catalyst poisons had leached from the polymers. Silver gauze discs were exposed to the stored hydrogen peroxide and the resulting discs examined using XPS to pick up any poisoning elements. As the result of these tests, FEP and PFA polymers were classified as Class I materials, with decomposition rates comparable to the best materials available. However, they are not significantly better than the 5254-0 or 5254-H34 aluminum alloys; in fact, based on these tests, the aluminum alloys should actually perform better. How-

ever, for spacecraft in orbit for long periods, the PFA and FEP liners complicate the storage problem due to the high rate of permeation. Even with a decomposition rate of 0.3% AOL, some form of tank venting will still have to be implemented, and this either requires a spin-stabilized spacecraft or a propellant management device, to separate the gas from the liquid.

Three small vessels were machined from fluoropolymers including unsealed lids of the same material to study hydrogen peroxide permeation [852]. They were filled partly with 85% HTP (stabilized at the time) and left undisturbed on a bench top at $294 \pm 1\text{ K}$ ($21 \pm 1\text{ }^\circ\text{C}$). A thin-walled PVDF vessel containing 125 g of HTP gained 8 g in 1.5 years and an additional gram over the following year. A 40-g sample in a thicker container gained 0.2 g over 4 months and then lost 0.9 g over 2 years. An identical thick-walled vessel made of PCTFE contained 42 g of HTP and gained 2 g over 2 years at a roughly constant rate. Of all the materials tested, PVDF clearly offered the most potential for 1-year sealed HTP storage. In this study, PVDF was studied as a liner material and was thought to be a good candidate until it started to peel. It was thought that the HTP permeated the plastic and decomposed between the metal and its coating.

Five polymers based on the polymerization of dicyclopentadiene were tested for compatibility with HTP [881]. Telene[®] 1650X was the most compatible polymer of five polymers immersed in high concentrations of HTP for 200 days. Telene[®] 1650BRR was the second best compatible, having similar effects on the HTP and less compatibility when being acted upon by HTP. Paramount 1 was the least compatible of the five polymers because it was greatly affected by HTP. The concentration of 90% HTP exposed to the polymers dropped from 90 to 70–80% during the 7-month test. Some of the polymer samples gained 10–20% weight during the immersion.

Much of the initial work with HTP was performed in the 1950–1960 time period. Since this time, new polymers have been introduced, some of which may avoid the storage problems of the past and may be more resistant to attack by HTP. More recent compatibility work performed with non-metals immersed in HTP has shown that it is often difficult to bring the results from different laboratories to a common denominator.

The most common polymer used for storage hydrogen peroxide is polyethylene (PE). Various sources specify that PE is a Class 1 or a Class 2 material, depending on the temperature of exposure. Most sources suggest that long-term storage in polyethylene is acceptable, as long as the peroxide concentration is no greater than 52% H_2O_2 . Kel-F (polychlorotrifluoroethene), or Neoflon[®], is also a common polymer for use with HTP. Most sources indicate that it is favorable for use as a diaphragm material in contact with HTP. Unplasticized Kel-F was tested as a tank material for a 275-gallon HTP tank for the US Navy, so there is some precedent in using Kel-F as a storage tank material [882].

Polyvinylchloride (PVC) is recommended only for short-term storage of HTP and is typically classified as Class 2 or Class 3 material, depending on the temperature.

PVC may also leach chloride ions into the HTP. Koroseal[®] is a PVC material that is generally not recommended for long-term HTP exposure. Koroseal 700, however, was developed especially for H₂O₂ service as a gasketing material, but it may no longer be manufactured.

Teflon[®] in its various forms (PTFE, PFA, and FEP) is the best choice of polymeric material in regard to HTP compatibility and can be used for storage of HTP, and it has often been cited as a Class 1 material. Many of the fluorinated polymers have been recommended as the best polymeric storage medium for HTP. They are recommended as a valving or sealing material as well. One of the problems with the fluorinated polymers is their lack of structural strength. For this reason, Teflon is more often recommended as a liner material than as an actual storage container material. The rationale for this justification is that if the container is somehow damaged, whether during transit or by general mistreatment, the fluorocarbon container would not provide adequate protection from damage.

Viton[®] A and B, fluoroelastomers, are typically used as O-ring materials for HTP storage tanks. They are not typically considered as a viable candidate as a tank wall material.

PVDF (polyvinylidene fluoride), or Kynar[®], was recommended as a possible alternative to PTFE compounds. In the study cited, which examined various polymers as tank materials, the concentration of an 87% solution of H₂O₂ decreased to 80% over 3 months (at 343 K = 70 °C). PVDF was the only polymer that maintained its durability characteristics [97].

PFA (Perfluoroalkoxy) and FEP have been examined in several studies and are both very promising candidates that may merit consideration. In two studies by the University of Surrey, PFA and FEP were examined in detail. They were good at containing peroxide, but their intrinsic compatibility was not as good as pure aluminum. However, such polymers do permit oxygen to permeate.

Compatibility tests indicated that many polymers decompose 90% hydrogen peroxide appreciably, while the effects of others were negligible. The appearance of some polymers remained unchanged after immersion in this oxidizer. The steady-state diffusion rate through several polymers was measured in a test apparatus constructed of Teflon [883]. The hydrogen peroxide, which permeated any film, was determined quantitatively by means of a spectrophotometric method. Experimental curves of the amount permeated as a function of time agreed with those predicted theoretically. A correlation was found between water vapor and hydrogen peroxide permeabilities for several polymers at room temperature. The hydrogen peroxide permeabilities of many polymers measured at 347 K (74 °C) over 96 h varied over four orders of magnitude. Teflon, Teflon 100-X, and polyethylene exhibited the lowest permeability of all the polymers tested. The temperature dependence of hydrogen peroxide permeabilities was found to conform to an Arrhenius type relationship. Activation energies for hydrogen peroxide permeation through plasticized polyvinyl chloride and polyvinylidene chloride were 66.9 and 75 kJ/mol (16 and 18 kcal/mol), respectively.

Short-term (240-h) immersion tests of polyformaldehyde (POM) and ultra-high molecular weight polyethylene (UHMWPE) in rocket-grade hydrogen peroxide solution were carried out in combination with tribological experiments [884]. The objective was to provide the knowledge for selecting or developing polymeric materials for tribological friction-wear applications in rocket-grade hydrogen peroxide. The micrographs of polymer specimens with various aging times indicated that POM had poorer aging resistance in hydrogen peroxide solution than UHMWPE. A new absorption peak assigned to the hydroxyl group appeared in the FTIR spectra of POM after aging tests due to the oxidation by hydrogen peroxide. The wear rates of POM and UHMWPE presented different trends with the increase of aging time; the wear rate of POM decreased, whereas the wear rate of UHMWPE increased.

5.4.2 Inorganic Ceramic Materials for Hydrogen Peroxide Service

Ceramic materials have been used for roller bearings and as coatings for metallic components in contact with hydrogen peroxide. Of course, ceramics are also used as catalyst carriers, but for that application, the contact time with liquid H_2O_2 is only very short because the liquid decomposes as soon as it contacts the catalyst.

Protective coatings of zirconium nitride deposited by plasma vapor deposition prevent corrosion of the metal parts, decomposition of HTP, and leaching of metal ions into the propellant [885].

Water and hydrogen peroxide are very poor lubricants for ceramic/metal pairs in sliding contact with each other as in the bearings of pumps and flowmeters. The wear patterns of ceramic/metal contact rubbing pairs in several hydrogen peroxide/water mixtures with increasing hydrogen peroxide content were evaluated by examining the wear surfaces and the abraded metal particles under the microscope [886]. The wear resistances of three types of ceramics (ZrO_2 , Al_2O_3 , Si_3N_4) rubbing against 1Cr18Ni9Ti stainless steel were analyzed under 0 (pure water), 10, 30, 50, 70, and 90% hydrogen peroxide solution. The results showed that, under different concentrations of H_2O_2 solution, the worn surface roughness of the 1Cr18Ni9Ti stainless steel was bigger than that under pure water when the counterpart was a ZrO_2 ceramic ball, while the worn surface roughness of the 1Cr18Ni9Ti stainless steel was smaller than that under pure water when the counterpart was a Al_2O_3 ceramic ball. For the ZrO_2 , Al_2O_3 , and Si_3N_4 ceramics balls, the average worn surface roughness of the Al_2O_3 ceramic ball was the smallest, and the average worn surface roughness of the Si_3N_4 ceramic ball was the worst when the concentration of H_2O_2 solution was only 10%. The metal particles from the ZrO_2 /1Cr18Ni9Ti and Al_2O_3 /1Cr18Ni9Ti stainless steel rubbing pairs showed wear features with large size and bright surfaces. The surfaces of the metal particles were visibly oxidized when the concentrations of H_2O_2 solutions were 70 and 90%.

Similar tribological friction pairs of Al_2O_3 ceramics in contact with 1Cr18Ni9Ti stainless steel were examined in hydrogen peroxide solutions of several different concentrations [887]. The wear mass loss of a 1Cr18Ni9Ti stainless steel ring sample in all

H_2O_2 solutions was worse than that in pure water. The wear mass loss was the worst in 70% H_2O_2 solution. Additional tests were performed with ZrO_2 , Al_2O_3 , Si_3N_4 ceramics and 1Cr18Ni9Ti stainless steel rubbing pairs in a tribo-tester under different concentrations of H_2O_2 solutions [888]. The rubbing pairs of Si_3N_4 ceramics/1Cr18Ni9Ti stainless steel had the best tribological properties in H_2O_2 solutions.

6 Components for Hydrogen Peroxide Service

This section describes components for ground handling and flight use of HTP. The design of test facilities for HTP rocket testing (monopropellant, bipropellant or hybrid rocket testing) has evolved over the years. Often, obsolete test facilities get torn down to be replaced with more modern test facilities with improved data acquisition and expanded capabilities.

Test facilities for HTP testing as a monopropellant are described in *Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide Monopropellants”; see also [867, 889, 890].

6.1 Storage Tanks for Hydrogen Peroxide Service

Hydrogen peroxide as it sits and slowly decomposes releases heat all the time. It has been argued that storage tanks for HTP should not be thermally insulated from the environment because if they were to have an unexpected exothermic reaction due to internal contamination, it would result in a runaway thermal reaction much faster. On the other hand, if storage tanks or tank cars or large transport tanks on ships became involved in an external fire, the fire department response time to a catastrophic tank rupture event would be extended if the tank had a fireproof thermal insulation. If a 4000-gallon tank containing 70 mass-% H_2O_2 became involved in an intense, enveloping fire, what happens during the first 30 min? In answer to this question, the response time for large 4000-gallon tanks on a ship containing 70% H_2O_2 was calculated from laboratory measurements of decomposition rates for a bare tank and an insulated tank [396].

Hydrogen peroxide storage tanks are normally fabricated with Class 1 materials. Most tanks used for bulk storage of H_2O_2 are made from aluminum 1060, which is 99.6% aluminum and very soft. When greater strength is required, aluminum alloys 5254 and 5652 can be used for bulk storage tanks. In consideration of the requirements for high-pressure lightweight tankage, AM 350 stainless steel has been used successfully, but only for short storage durations. The 17-7 precipitation hardening stainless steel has been used successfully in closely monitored 76 and 90% H_2O_2 systems. However, this material is generally more difficult to passivate than the AM 350 material, particularly when used in 90 and 98% H_2O_2 systems. Both steels offer yield strengths

of 160000 psi. The hydrogen peroxide tankage used in rocket test facilities and various other feed and ready storage applications (which required only short periods of hydrogen peroxide storage) is usually fabricated from 347 stainless steel. Other materials successfully utilized in tankage for these types of applications are the low-carbon 304, 316, and 321 stainless steels. The cryogenic prestrained 301 stainless steel has demonstrated excellent compatibility with 90 and 98% H_2O_2 , and the high yield strength of this material (260 ksi) favors its use for hydrogen peroxide tankage in flight vehicles and for high-pressure applications.

The material specifications of the containers for storage and delivery of high-purity aqueous hydrogen peroxide solutions for the electronic industry, container washing, and contaminant inspection methods are important to preserve the purity of the material. The containers of Mitsubishi Gas Chemical Co., Sumitomo Chemical Co., and Aisero Chemical Co. used for storage and delivery of high-purity aqueous hydrogen peroxide solution were compared [891].

In short-term storage tests evaluating four different materials for a breadboard test system tank with 98% H_2O_2 , pressure buildup due to gas evolution in contact with Al-6061, anodized Al-6061 or polycarbonate exceeded 15 bar in only 15, 33, or 52 days [892]. A tank made from polyvinylidene fluoride had the lowest rate of gas evolution, reaching 8 bar in 170 days, which is still too high for any type of space mission.

6.1.1 Flightweight Tanks for Hydrogen Peroxide Service

A composite tank using an epoxy resin and graphite fibers shell was fabricated for use in the space program. If HTP is to be used as the oxidizer, FEP (fluorinated ethylene/propylene) is recommended as the liner material [893].

The US Air Force has done work with a composite fuel tank for storage of HTP as well in connection with their Space Maneuver Vehicle (SMV) Program, with a “Teflon-like” liner [894].

For the Upper Stage Flight Experiment using a 90% HTP/JP8 engine, an integral composite carbon fiber overwrapped tank was designed, built, and hydraulically pressure tested to destruction [895]. The Upper Stage Flight Experiment was a technology demonstrator for the US Air Force’s operational Modular Insertion Stage (MIS). MIS was to be a low-cost expendable upper stage for the reusable space operations vehicle. The tank had the following dimensions and design parameters:

overall length	45.0 in.
skirt ID	24.0 in.
oxidizer chamber volume	5.5 cubic feet
fuel chamber volume	2.3 cubic feet
MEOP	800 psi
proof	$\text{MEOP} \times 1.25$
burst (minimum)	$\text{MEOP} \times 1.8$

The liners for both oxidizer and fuel were initially intended to be Tefzel but were later changed to PVDF. The bosses were from 316L stainless steel. During the hydraulic pressure burst test, the fuel liner failed at 2500 psi, allowing water to flow through the composite overwrap. Failure at 2500 psi showed a realized safety factor of 3.1 (the design was 1.8); see also [896, 897].

6.1.2 Expulsion Diaphragms and Bladders for Hydrogen Peroxide Service in Zero-g

It is difficult to find a polymer for expulsion bladders for hydrogen peroxide that is compatible with the aggressive oxidizer and does not embrittle with time or contaminate the propellant with leached organics [898, 899]. These tanks were to be used in the four-stage solid propellant Scout satellite launch vehicle.

A commercial off-the-shelf bladder propellant tank was tested with hydrogen peroxide and found to be acceptable for “long-term” storage of the hydrogen peroxide with only minimal pressure rise during storage [900]. “Long-term” needs to be identified more accurately and may only be a matter of a few months.

The first six satellites of the FORMOSAT-7/ COSMIC-2 satellite constellation developed by the National Space Organization (NSPO) program of Taiwan used a hydrazine monopropellant system, but a future constellation was planned to have a 2-liter diaphragm type propellant tank with a loading capacity of 1-liter HTP [901]. Two engineering qualification models were designed, manufactured, and tested to make sure that they will meet the satellite mission requirements.

6.1.3 Tank Pressurization and Feed Systems for Hydrogen Peroxide Service

A self-pressurizing hydrogen peroxide rocket system using a differential area piston tank boot-strap propellant feed system was demonstrated using 87% hydrogen peroxide feeding a ~50 lb_f monopropellant thruster or a hybrid rocket [902]. It used a differential area piston tank and a gas generator to enable self-pressurization. A small amount of HTP was tapped off the propellant tank, flowed through a gas generator, and pressurized the propellant tank in a bootstrap mode using the decomposed HTP. The steam and hot O₂ pressurized the top of the differential area tank, moving the piston down, expelling HTP into the larger, main rocket engine, and maintaining feed pressure in the tank although propellant is withdrawn from it. Multiple system tests indicated that a closed-loop peroxide system can bring a system up to operating pressures of 1.37–3.44 MPa (200–500 psi) from an initial supply pressure of as low as 0.34 MPa (50 psi). Preliminary analysis indicated that a boot-strap system could be 2 to 12 times lighter than a traditional inert gas pressurization system. The system described is equally applicable to hydrazine propellants.

6.2 Pumps for Hydrogen Peroxide Service

Differential piston area propellant feed systems (“bootstrap systems”) have been developed and demonstrated for hydrazine as well as for hydrogen peroxide. In the case of hydrogen peroxide, the hot gas pressurized the piston tank. One design used a cylindrical tank assembly having two different diameters and a compound internal piston [903]. The pressurant gas acted over an area larger than the liquid piston to amplify pressure. In effect, such a pump is a refillable differential piston tank. The pump must shuttle back and forth, and hence it has valves for receiving and discharging both liquid and gas. A self-pressurizing feed system with reciprocating 85% HTP pumps was designed, built, and integrated in a complete maneuvering system that could be used in a kinetic kill vehicle or a microsatellite mockup since it can translate and rotate in all three directions of space with its complement of thrusters [903]. It was then tested on a linear track where the vehicle was suspended on a frictionless air cushion. Some of the hot gas from the gas generator was diverted to small hot gas thrusters providing four-degree-of-freedom attitude control.

The friction and wear behavior of 1Cr18Ni9Ti stainless steel, which may sometimes be used for pumps or other components, depends on the concentration of hydrogen peroxide [904]. The tribological properties of 1Cr18Ni9Ti stainless steel and the chemical composition of the passive film in different concentrations of hydrogen peroxide were studied by measuring surface potentials by electrochemical measurements and X-ray photoelectron spectroscopy [905]. The wear behavior of 1Cr18Ni9Ti/GCr15 steel rubbing pairs was investigated using a pin-on-disc tribometer. The results indicated that the corrosion resistance of nitric-acid-passivated 1Cr18Ni9Ti increased significantly due to the existence of passivation film, which was mainly composed of chromic oxide. Moreover, 1Cr18Ni9Ti passivated with diluted nitric acid exhibited lower friction coefficient and higher wear resistance than unpassivated steel in hydrogen peroxide. It was suggested that the main wear mechanism was a combination of adhesive wear, abrasive wear, and corrosive wear for the passivated and unpassivated 1Cr18Ni9Ti in different concentrations of hydrogen peroxide.

The wear and tear at the interface between ceramic bearings and moving metal parts depends on the type of materials and the strength of hydrogen peroxide that they are immersed in. The wear of three types of ceramics (ZrO_2 , Al_2O_3 , Si_3N_4) rubbing against 1Cr18Ni9Ti stainless steel was measured while immersed under 0% (pure water), 10, 30, 50, 70, and 90% H_2O_2 solutions [906]. The results showed that, under different concentrations of H_2O_2 , the worn surface roughness of the 1Cr18Ni9Ti stainless steel was worse than that under pure water when the counterpart was a ZrO_2 ceramic ball, while the worn surface roughness of the 1Cr18Ni9Ti stainless steel was better than that under pure water when the counterpart was a Al_2O_3 ceramic ball. For ZrO_2 , Al_2O_3 or Si_3N_4 ceramic balls, the average worn surface roughness of Al_2O_3 ceramic ball was the smallest, and the average worn surface roughness of Si_3N_4 ceramic ball was the worst.

A study of the wear of rubbing pairs of 2Cr13 stainless steel against 1045 metal in HTP, the decomposition and damage mechanism of materials, friction coefficients, wear mass loss, worn surface topographies, and electric current densities was conducted under different concentrations of H_2O_2 solutions [907]. There were significant differences in the tribological behavior and electrochemistry properties of the rubbing pairs in different H_2O_2 solutions.

The corrosive and tribological behaviors and the wear mechanisms and alloy grain structure effects of AlCoCrFeNi alloys under 90 mass-% H_2O_2 solution in contact with Si_3N_4 ceramics were examined [908]. Alloys with poorer corrosion resistance and higher strength could more easily achieve effective lubrication. The component inhomogeneity of different grain structures may promote the corrosion behavior.

The selection of sealing rotary seals in HTP pumps and valves is a difficult task [909]. Many HTP accidents have been caused by leaking seals and gaskets.

6.3 Pressure Relief Devices for Hydrogen Peroxide Service

The preferred emergency pressure relief device for hydrogen peroxide systems is a rupture disk because it does not involve any moving parts. The relief device should be rated at not more than 100% of the vessel or system operating pressure when used as a primary relief device or 105% when used as a secondary relief device. The sizing of the device should be large enough to prevent the pressure from rising 10% above the maximum allowable working pressure of the system under any projected condition. Burst relief devices on hydrogen peroxide tank cars are designed to relieve at 310 kPa gauge (45 psig) pressure.

Ball valves intended to be used for hydrogen peroxide service must have a provision to relieve the pressure likely to build up in the passage through the ball while it is closed on both sides, and liquid is trapped inside.

6.4 Flow Meters for Hydrogen Peroxide Service

The performance of any bipropellant rocket depends on accurate metering of the oxidizer and the fuel flow into the engine. For an HTP/kerosene engine, a differential pressure orifice flowmeter has been used to measure the propellant flows [910].

6.5 Filters for Hydrogen Peroxide Service

Filters are extremely important with HTP systems [911]. The function of a filter is to trap particulate contaminants, and most contaminants are catalytic with HTP; therefore a filter with accumulated particulate contaminants will slowly turn into a catalyst bed

and become a hotspot which is very dangerous. For complex test systems, especially those using cavitating venturi, small injector orifices or other contamination-sensitive components, filtering the HTP may be a necessity to keep out foreign material. HTP storage vessels and transfer equipment can contain particulate contamination, such as aluminum oxides, phosphates, Teflon tape shreds, metal burrs, wire, or weld slag metal oxides. If a filter is used it should be considered a high-risk component and not a passive part of the transfer system. Additional precautions should be used to monitor the behavior of the filter through periodic inspections, temperature (hotspot) measurements, pressure drop measurements, and occasional backflushing.

The inlets to propellant valves are usually protected by filters to retain particles that might get lodged on the valve seat and cause the valve to leak when it is commanded shut. The screen material on the filters must be compatible with the propellant, which in the case of HTP is not as difficult a task as with other oxidizers. The corrosion product (phosphate, oxide) film growing on the thin metal wires might cause a narrowing of the passages and increase the pressure drop or embrittle the wires. Similar wire mesh is used in surface tension propellant management devices in propellant tanks for zero-g operation. The long-term effects of propellant immersion on fine micronic stainless steel wire cloth were studied for HTP and eight other propellants [912]. Immersion time histories reported in the literature ranged from 3 months to 7 years.

7 Handling of Highly Concentrated Hydrogen Peroxide

With sufficient experience and well-trained personnel, HTP can be handled safely. Nevertheless, like most other rocket propellants, the handling of HTP is not without its specific set of hazards. The attempt by some rocket enthusiasts to classify HTP as a “non-toxic” “green” propellant does not adequately reflect the true potential hazards in handling this material. Hydrogen peroxide was one of the first rocket propellants tested, and its handling experience for rocket applications spans a range of over 75 years.

After green propellant and improved propulsion systems performance initiatives identified hydrogen peroxide (HTP) as a candidate propellant for propulsion and power systems, NASA Johnson Space Center (JSC), White Sands Test Facility (WSTF), began to develop a hydrogen peroxide reference document to be used by academia, the industry, and government installations. The purpose of this document was to provide a central source of information to enable the user to assess HTP hazards. While there were several mostly historical sources of HTP hazards assessment documents, they were all dated to before 1969, and therefore may not utilize data and other information necessary for modern materials selection processes or adequately address recent concerns and current regulatory requirement. Recognizing these issues, an effort was initiated to produce a more up-to-date HTP hazards manual.

Various presentations discussed the interim status of this program [913] until it was completed in 2005 [914]. The most complete and very detailed summary of the fire, explosion, compatibility, and safety hazards of hydrogen peroxide was compiled by NASA WSTF in 2005 [10]. This 300-page document exceeds all previous hydrogen peroxide manuals and handbooks in its thorough approach to document potential handling hazards, critical analysis of historical data reported in the literature, and reporting of additional new safety data obtained at NASA WSTF during the past decade. The *Fire, Explosion, Compatibility and Safety Hazards of Hydrogen Peroxide* NASA technical manual covers various topics concerning HTP, including fire and explosion hazards, material and fluid reactivity, materials selection information, personnel and environmental hazards, physical and chemical properties, analytical spectroscopy, specifications, analytical methods, and material compatibility data. A summary of HTP-caused accidents, incidents, close calls, mishaps, and lessons learned is included in the hope that this information will prevent future incidents of this type. Hydrogen peroxide users are cautioned when extrapolating from short-term compatibility test results to long-term compatibility predictions.

For additional historical information on the handling of hydrogen peroxide see the following now mostly antiquated references: [915–920].

A series of papers published by General Kinetics LLC during the period 1998 through 2007 set out to dispel some of the misconceptions and myths about hydrogen peroxide [840, 911]. General Kinetics Inc. ceased operations as of the end of the first quarter in 2012; see also [921].

7.1 Transport and Storage of High-Test Peroxide

7.1.1 Transportation of High-Test Peroxide

The transportation of solutions with >52 mass-% H_2O_2 within the US was regulated by 49 CFR § 173.266 [922, 923]. This rule has been updated periodically. Specification 42D describes Al drums with a vented closure in top head, not over 208 L (55 gallons), capacity. The drums must be marked “KEEP PLUG UP TO PREVENT SPILLAGE”.

7.1.1.1 US Transportation Regulations for Hydrogen Peroxide

Hydrogen peroxide solutions above 8% H_2O_2 are classified as “oxidizers” by the US Department of Transportation, and all containers must bear the yellow oxidizer DOT label.

Hydrogen peroxide, stabilized or hydrogen peroxide aqueous solutions, stabilized with more than 60% hydrogen peroxide are covered under UN2015, Hazard Class 5.1, but it does not state the maximum concentration allowed under this code. Special permits have been issued for transportation of hydrogen peroxide with more than 62% but less than 92% H_2O_2 [924].

As of 1999, Degussa-Hüls Corp. (a predecessor to Evonik) had safely shipped 90% HTP in the US in a variety of containers [925].

The US Department of Homeland Security (DHS) has classified H_2O_2 as a Chemical of Interest (COI) due to being a candidate for “theft and diversion”. Special regulations apply in that a H_2O_2 bulk transport vehicle may not be left unattended. Theft and diversion calculations for screening threshold quantities (STQ) of H_2O_2 have been published in 6 CFR 27.203(c), typically starting at 35%/400 lbs; which further states that chemicals in “transportation packages” are to be used for the STQ calculation.

7.1.1.2 Tanker Trucks and Railcars

The requirements for bulk packaging of high-hazard liquids are given in 49 CFR Part 173.243. The definition of bulk packaging includes railcars, cargo tanks (tanker trucks), and intermediate bulk containers (tote bins). Larger quantities of HTP are transported in tank cars in compliance with regulation ICC-103A-AI-W made of aluminum alloys. Such tank cars hold 15000 to 30000 L. In both Europe and the United States, all hydrogen peroxide shipped at concentrations exceeding 72% is subject to strict regulation in terms of the permissible means of commercial transportation. The International Maritime Dangerous Goods (IMDG) Code (which regulates international sea transportation) and the United States Department of Transportation regulations for bulk shipments of hydrogen peroxide over 72% concentration are not consistent in terms of bulk transport of HTP. The Degussa Corporation has petitioned the US Department of Transportation (DOT) for an exemption to the current regulations covering bulk shipments of high-strength hydrogen peroxide. If granted, this would allow transport of HTP within the continental United States in full truckload quantities using especially designed bulk containers. Table 60 summarizes some of the 1998 packaging and transportation options for HTP permitted under the applicable body of law.

High-strength hydrogen peroxide falls under the shipping classification 5.1, UN 2015, and PG 1, and must be transported and labeled in conformity with the specifications and standards provided in 49 CFR § 171–190 (various subsections) and the

Table 60: Transportation regulations for hydrogen peroxide.

Packaging	UN code	Volume	Land (Europe)	Sea (ex Europe)	Land (USA)
Combi-drum (PE lined steel)	6HA1	125 L	Not allowed	Partially Allowed	Allowed
		250 L	Not allowed	Not allowed	Allowed
Steel drum	1A1	125 L	Allowed	Allowed	Allowed
		250 L	Not allowed	Not allowed	Allowed
Aluminum drum	1B1	125 L	Allowed	Allowed	Allowed
		250 L	Not allowed	Not allowed	Allowed
Combi IBC	31HA1	1000 L	Not allowed	Not allowed	Not allowed
Steel bulk tank		varies	Allowed	Allowed	Not allowed
Combi bulk tank		varies	Allowed	Allowed	Not allowed

IMDG Codes. The 5.1 classification indicates a primary hazard as an oxidizer, with a subsidiary hazard (8) as a corrosive material. The product cannot be shipped by air under the controlling authority of IATA (for civilian carriers) and AFMAN 24-204 (for military air transport).

7.1.1.3 Storage of High-Test Peroxide

Four grades of Becco hydrogen peroxide were evaluated during an extended storage test: commercial 90 mass-% H_2O_2 , propulsion Grade 90 mass-% H_2O_2 , commercial 98 mass-% H_2O_2 , and propulsion Grade 98 mass-% H_2O_2 in 3.78-L (1-gallon) capacity TFE Teflon bladders were contained in mild steel test tanks at 294–295 K (70–72 °F) for 5 months, 322 K (120 °F) for seven days, and 347 K (165 °F) for 72 h [926]. The bladders were not as compatible as desired due to the bleaching and crack development experienced with this dispersion-type Teflon. These tests showed that the oxygen loss from the H_2O_2 during the storage period can be decreased by utilizing improved passivation techniques, surface pretreatment techniques, and improved stabilizers for the H_2O_2 . The use of an oxygen absorbent bag in the tank proved non-rewarding due to breakdown of the absorbent solution. The most promising test results were obtained with the 98% propulsion grade H_2O_2 containing stabilizer “P”. Brief screening tests showed other bladder materials such as NAA Vicone 185, 3M Fluorel #2141, and Dupont Viton B cure 805 to give comparable or superior compatibility in contact with the H_2O_2 when compared to the dispersion-type Teflon material.

Drums

Non-bulk packaging (i.e., drums) available from the former Degussa-Hüls Corporation complies with 49CFR Part 178 (DOT). These drums are 125-L type UN 6HA1, constructed of stainless steel with a high-density polyethylene molded inner liner. While these may suffice for 90% HTP, an incident at NASA Stennis when the same drums were used for storage (not shipment outside the facility boundary) of 98% HTP and started an exothermic reaction after the HTP had permeated the PE liner and came into contact with stainless steel, **cautions us not** to use these drums for higher (>90%) concentration HTP. The IMDG (International Maritime Dangerous Goods) Code only approves 1A1 (inert, steel) and 1B1 (inert, aluminum) drums for the transport of hydrogen peroxide of 60% or higher. However, at one time, Degussa-Hüls has had a special approval to use 6HA1 drums for shipping HTP containing up to 90.5% H_2O_2 .

A nicely illustrated summary of various HTP transportation and storage vessels is shown in [911], which is based on experience at General Kinetics LLC and FMC.

HTP is normally shipped in 110-L barrels made of aluminum and complying with ICC regulation 420, UN 2015, typically containing 115 kg of product. Numerous storage tests have shown that HTP loses no more than 1% H_2O_2 (absolute) per year in properly built, cleaned, and passivated drums that also have a pressure relief valve to vent any pressure buildup [927, 928]. The 144-L barrels were of the Type 42 D and made of 99.6%

Al, Al-525, or Al-XF-52S. The gasket and valve seat material on the pressure relief valves was a silicone rubber.

It is prohibited to place wooden pallets under hydrogen peroxide drums with $>27.5\%$ H_2O_2 .

ISOtainers

ISO's IM tanks, also called ISO containers or ISOs, are used by Degussa-Hüls to transport bulk quantities of Propulse™ H_2O_2 . ISOs are classified as IMO tank type 1 and DoT type IM 101. While it is approved to ship H_2O_2 concentrations greater than 72-mass-% internationally, domestic US transportation in IM 101 tanks is restricted to 72% or less by 49 CFR Part 172. The Degussa-Hüls Corporation has obtained exemption DOT-E 12003 to allow the transport of up to 92 mass-% H_2O_2 in IM 101 tanks and has delivered Propulse™ HTP in bulk domestically over the road.

ISO containers are ASME-coded vessels enclosed in a steel-tube framework that makes them safe and easy to handle as ocean and over-the-road freight [97]. ISOs have the following physical parameters:

- dimensions: 20 ft. long $\times$ 8 ft. wide $\times$ 8 ft. high
- capacity: 24000 kg (52800 lb) gross weight
- 20000 kg (44000 lb) payload weight
- 14280 liters (3780 US gallons) max. payload

Storage tanks (not tank car tanks) should be made of 99.6% Al or XF-52-S-Al, Al-1060, Al-5652 or Al-5254, with pipes of 99.6% Al or Al-2S. Valves and pumps can be made of 99.6% Al, Al-2S, or Al-43S. CRES-316 is not suitable for this purpose.

Due to the lack of other materials during WWII in Germany, plastic-lined steel containers were used for storage of H_2O_2 and were in use for several years [929].

If the pressure in storage drums (regardless of what the drums are made of) is not monitored regularly, and the pressure relief valves become stuck closed, excessive pressure buildup can rupture the drums [930, 931]. Figure 56 shows the consequences of premature hydrogen peroxide decomposition in a storage drum that was not properly vented. One can see how the sides of the drum bulged before it ruptured on the lid.

Figure 56: Ruptured HTP storage drum. (From [931].)

For this reason, H_2O_2 storage tanks should carry a pressure gauge and a pressure relief valve. Descriptions of the design of complete HTP storage and transfer facilities can be found in the literature [867]. HTP manufacturers will often assist their customers in the design of storage and transfer facilities and provide training for propellant handling personnel.

Only few climates will have outside storage temperatures below the freezing point of HTP. It has been observed that due to the high purity of HTP, the liquid tends to supercool, and it is often remaining in the liquid state at temperatures where theoretically it should be frozen. The unpleasant side effect of freeze-thaw cycles might be stratification and segregation, which cause a layer of the contents to approach higher H_2O_2 concentrations than what is printed on the label. The contents of drums retrieved from subfreezing storage would have to be thoroughly mixed before taking a sample for analysis or before withdrawing material for use. If all of the contents are transferred from one tank into another, enough turbulence will usually occur to result in a thoroughly mixed contents with uniform concentration throughout in the receiving vessel.

Contrary to water, H_2O_2 does not expand on freezing. So, at least, there is no drum rupturing hazard if the contents are inadvertently frozen. However, transporting drums with slugs of solid H_2O_2 over rough roads may subject the bottoms of drums to excessive impact loads from the slug of H_2O_2 ice for which they were not designed.

If it is mission critical to keep an HTP supply from freezing in arctic regions away from electric power supplies, a method of drum heating has been designed that sacrifices part of the drum contents, using its controlled decomposition as a heat source [932].

Small amounts of contaminants can cause a self-accelerating runaway situation where the heat evolved by decomposition of the contents exceeds the heat that can be conducted away through the walls of the containers. Thermal explosions have been studied, and methods for prevention of unwanted explosions have been developed [930, 933]. Figure 57 shows the predicted temperature history of a large storage container with contaminated HTP. For this calculation, a decomposition rate of 50%/year, outside and at the initial liquid temperature $298\text{ K} = 25^\circ\text{C}$, and a surface : volume ratio of 1 m^{-1} was assumed. The ambient air condition was stagnant air. A decomposition rate of 50%/year is rarely encountered and can only be the result of gross negligence [934]. But what can one do if a tank shows a temperature increase? One can try to add more stabilizer, cool the tank, dilute with water (if space is available in the tank), or drain the tank into a large holding pond with enough water to dilute the tank contents to below 5% H_2O_2 . Some storage and rocket test installations have H_2O_2 disposal reactors where surplus HTP can be decomposed and disposed of (see *Encyclopedia of Monopropellants*, chapter “Hydrogen Peroxide Monopropellants”).

Figure 57: Predicted temperature increase in an HTP storage container due to an incipient uncontrolled decomposition/runaway situation. (Reproduced and modified from [930].)

HTP Storage

In Russia, where HTP is still actively used in the reaction control system (RCS) of Soyuz space capsules and steam generators in the Soyuz launch vehicle, HTP storage tanks are loaded to only 90% of their capacity during winter and 85% of their capacity during summertime [935]. HTP in quantities up to 100 m³ is stored in aluminum tanks. The tanks are thoroughly passivated before their first loading. During the whole storage period the internal HTP temperature must not exceed the ambient temperature (a warning sign of incipient decomposition), and it must not exceed 298 K (25 °C). In any case, if the HTP temperature reaches 303 K (30 °C), cold water must be sprayed over the storage tank to cool it from the outside. If the idle period of unused tanks, lines, and pumps exceeds 6 months, the equipment is washed out periodically with 30% H₂O₂ aqueous solution. During long-term (10–15 years) storage in very large (>2 m³) aluminum tanks, HTP (96–98 mass-%) decomposed approximately only 0.05% per year at 283–298 K (10–25 °C). Based on the operational experience in Russia since the early Vostok and Soyuz flights, 10-year storage on the ground is considered quite acceptable; see also [936].

A decrease of HTP self-decomposition during its storage can be achieved by saturating it with highly soluble gases. A significant decrease in HTP self-decomposition rates was observed when it was saturated with carbon dioxide.

NFPA Hazard Ratings

A rating system has been devised by the National Fire Protection Association (NFPA) to assist emergency responders – NFPA 704-1990. The system has also been incorporated into the Uniform Fire Code, Standard 79-3. This program utilizes a color-coded tank/site placarding system that visually alerts first responders to the types of hazards associated with the material (e.g., health, flammability, and reactivity). The appropriate labeling for various H₂O₂ concentrations is shown in Table 61.

Table 61: NFPA hazard diamond classifications for hydrogen peroxide.

H ₂ O ₂ Concentration, mass-%	Health	Flammability	Reactivity
<8	0	0	0
8–20	1	0	1
20–52	3	0	1
52–91	3	0	2
>91	3	0	3

The NFPA Diamond hazard label for hydrogen peroxide above 52 mass-% contains:

- health: 3 (blue section)
- fire: 0 (red section)
- reactivity: 2 (yellow section)
- specific hazard: OXY (white section)

7.1.1.4 Transfer of High-Test Peroxide

HTP can be transferred from one container to the other using pumps or vacuum suction transfer [937].

Very rarely will one be in a situation where one can use gravity flow from a higher positioned supply tank into another tank. The supply tank at grade (normal situation) or below grade (more severe situation due to hydrostatic head) must be rated to withstand the transfer pressure. Some transportation drums are not intended to be pressurized. Suitable pressurant gases are air, nitrogen, oxygen, argon, or helium.

The former Degussa-Hüls specified that product must be pumped out of the drums; the drums are not to be pressurized under any circumstances. Self-priming centrifugal or positive displacement (e.g., diaphragm or peristaltic) pumps are the best choices. Drum pumps are acceptable but normally employ an impeller at the bottom of the dip tube, thus preventing complete discharge of the product from the dip tube and downstream system. Where a vacuum system is used to convey product from the drum, the vacuum source must be an air-driven venturi, not a mechanical, oil-lubricated vacuum pump. Accidental conveyance of HTP into a vacuum reservoir or pump could result in an explosion.

7.2 Personnel Protective Equipment for Handling of High-Test Peroxide

Protective clothing worn by propellant handlers must be made of non-combustible splash-proof material. It has been shown that some of the not-so-suitable glove and apron materials will catch fire when HTP is sprayed onto them [938, 939]. The suitability of personnel protective equipment (PPE) for HTP service was determined by observations made when HTP was dripped onto swatches of protective clothing material. Samples of ten different chemical protective materials were cut into 4 in. by 4 in. swatches and tested as-received, in soiled condition and in grossly soiled condition. Materials were soiled by pretreating the material with potassium permanganate (KMnO_4) solution and then drying it to make the fabric a worst-case situation. Grossly soiled material samples had solid KMnO_4 sprinkled over their surface. Observations included visual changes to the hydrogen peroxide and materials, times to ignition, and self-extinguishing characteristics of the materials. All of the grossly soiled specimens ignited within 2 to 100 s when 98% HTP was dripped on them. In tests with clean materials, only leather ignited.

A complete HTP propellant handler's ensemble consists of a face shield and head cover, coverall, apron, gloves, and boots. Gas masks or respirators are normally not required.

A comprehensive summary of protective clothing for all types of corrosive chemicals, and the hazards of permeation of aggressive chemicals through the protective clothing during use is provided in [940] and [941].

7.3 Fire Fighting of High-Test Peroxide-Sustained Fires

Fires sustained by HTP and spilled fuels or combustible materials of storage buildings are best extinguished with copious amounts of water. Water will not only cool the flames but also dilute HTP to below the point where it can sustain combustion. Spilled HTP prior to ignition should also be diluted with water to below 30% before a cleanup is attempted. During the spill cleanup there may be an acute and a delayed ignition hazard.

7.4 Treatment of High-Test Peroxide Spills and Rinse Waters

Hydrogen peroxide is used in the dairy industry for the pasteurization of milk and equipment prior to cheese making. Excess hydrogen peroxide must be removed before the milk can be passed on to the next step of cheese making. The most benign and environmentally compatible way to remove small concentrations of H_2O_2 in dilute solutions would be with the enzyme catalase. However, the enzyme either in the soluble form or immobilized on a support degrades quickly. It has been attempted to

employ longer lasting catalysts made from manganese oxide on alumina that do not leave residues in the milk [942, 943]. The activity of the manganese oxide/alumina catalyst degraded quickly initially but leveled off after some time; see also [944].

7.5 Disposal of Surplus Hydrogen Peroxide

Surplus hydrogen peroxide that is no longer needed or is of a questionable pedigree or has become accidentally contaminated, or hydrogen peroxide that has been used to passivate a new tank can be disposed of in dedicated stationary hydrogen peroxide disposal reactors. Several of these disposal reactors have been installed at rocket test facilities in the US.

One such reactor was built by General Kinetics for NASA. It used MnO_2 pellets, which are much more economical than silver or stainless steel screen but would not qualify for use in flight thrusters. As of 2001, in one of these installations about 4500 kg (10000 lb) of surplus H_2O_2 with concentrations ranging from 50 to 98% was disposed of [945].

Our primary interest here is in the disposal of HTP, but there is a more widespread need for the disposal of hydrogen peroxide in dilute solutions that are widely used in industry and in the sterilization of medical equipment and contact lenses. There are many patented catalysts and methods for the disposal of hydrogen peroxide in dilute solutions. These catalysts are only capable of operating at low temperature and are useless for rocket applications.

7.6 Gelled Hydrogen Peroxide

Hydrogen peroxide, like other liquid rocket propellants, can be gelled to suppress sloshing of liquids in propellant tanks during the ascent phase of a rocket or to prevent leakage. This would be done only in cases where hydrogen peroxide is used as an oxidizer in bipropellant or hybrid rockets.

The rheological behavior of gelled hydrogen peroxide at different ambient temperatures (283, 293, and 303 K) in the shear rate ranges of 1 to 20 s^{-1} and 1 to 1000 s^{-1} was characterized using a rheometer [946, 947]. Six mass-percent of fumed silica (SiO_2 , 0.2–0.3 μm aggregate, Sigma Aldrich Corp.) was used for the gelation of hydrogen peroxide. As with all thixotropic fluids, the apparent viscosity with some yield stress (in the case of shear rate 1 to 20 s^{-1}) fell drastically with the shear rate. In the case of the shear rate range of 1 to 20 s^{-1} , the apparent viscosity and yield stress of the gel were significantly reduced at higher ambient temperatures. In the case of the shear rate range of 1 to 1000 s^{-1} , no significant effect of varying the ambient temperature on the gel apparent viscosity was observed. The up and down shear rate curves for hydrogen

peroxide gel formed a hysteresis loop that showed no significant change with variation in temperature for both the 1 to 20 s^{-1} and the 1 to 1000 s^{-1} shear rate ranges.

The gelling agent in gelled hydrogen peroxide may interfere with catalysts if hydrogen peroxide is predecomposed in a catalytic reactor to ignite a hybrid rocket [948].

7.7 Histories and Anecdotal Accounts of Incidents Involving Hydrogen Peroxide and Hydrogen Peroxide Mixtures

In this summary of accidents, we have listed explosions and accidental overpressurization of tanks containing hydrogen peroxide or hydrogen peroxide mixtures with insufficient venting capacity. Not all these events were true detonations, and some can be categorized as “overpressurization” rather than an explosion [949].

On July 16, 1934, in Kummersdorf, Germany, a rocket engine using hydrogen peroxide exploded, killing three people. As a result of this incident, Wernher von Braun decided not to use hydrogen peroxide as an oxidizer in the rockets he then developed after the development group moved to Peenemünde.

After WW-II, a German rocket scientist captured and involuntarily transferred to the UK after WW-II, Dr. Johannes Schmidt, was killed in an accident at the D Site at Westcott, UK on 14 November 1947. It is sadly ironic that this occurred while he was testing one of the few pieces of impounded German WW-II hardware (a Walter 509-510 engine) that were ever fired at Westcott [950].

During the development of the LR-40 HTP/JP-5 bipropellant engine at RMD/Chance-Vought, the HTP decomposition product steam-driven turbine was on the same single shaft as the two propellant pumps. The two pump seals shared a leakage collection cavity that should have had the drain opened during operation. An accident was caused by not removing a pump shaft leakage collector cavity drain plug prior to testing. A mixture of 90% HTP and kerosene that had leaked accumulated in the cavity and exploded when the drain plug was removed after the test, killing one technician and injuring several bystanders [951].

An accident occurred during the treatment of a surfactant with a peroxide/water solution that was usually highly diluted [952]. Due to several circumstances, a more concentrated solution was inadvertently applied at startup of the unit. This caused a sudden pressure increase, which burst a pipe, releasing large quantities of heating fluid, which caught fire. The fire destroyed the unit. In trying to explain what happened, the sudden pressure increase was simulated in the lab and the heat release measured by thermochemical methods. It was demonstrated that even concentrations of hydrogen peroxide as low as 10 mass-% in a homogeneous solution with organic material can cause sudden pressure increases in excess of the regular rating of most apparatus used in the chemical industry and high rates of pressure increase.

The author of a Russian book on fast reactions in energetic materials and high-temperature decomposition of rocket propellants and explosives [432] states

on page 173: “Based on his personal experience of working in committees that have investigated many accidents, the author of this book came to the conclusion that h/c H_2O_2 can be considered the most dangerous (with respect to explosions and fire hazards) liquid propellant component, especially in monopropellants. This conclusion is backed up by the following relatively recent serious accidents” and continues to list several accidents which he personally investigated.

An accident in the Russian submarine *Kursk*, which sank in the Barents Sea, involved a highly concentrated H_2O_2 -fueled torpedo explosion. Before this accident, on 18 March 1980, an A-7 rocket exploded during fueling, killing 48 people at the Plesetsk spaceport. As was discovered by Shteinberg, the accident was caused by the thermal explosion of HTP H_2O_2 that came into contact with catalytically active Pb-containing solder. The soldering alloy was mistakenly used by a manufacturer to solder a stainless-steel screen filter in the HTP H_2O_2 supply line.

Hydrogen peroxide is used during the reprocessing of nuclear reactor fuel elements to precipitate the separated plutonium in the form of plutonium peroxide. Two accidents happened at the EG&G-operated Rocky Flats Plant in 1957 and 1980, where 35–50% H_2O_2 became contaminated, and rapid decomposition overpressurized the reaction vessels and spilled plutonium outside the glove boxes [420].

Prior to 1963, a chemist was killed when he inadvertently poured highly concentrated hydrogen peroxide into a laboratory sink. The hydrogen peroxide reacted violently with some U-DETA (MAF-4, a mixed amine fuel consisting of unsymmetrical dimethylhydrazine (UDMH) and diethylene triamine (DETA)) remaining in the trap underneath the sink, and the trap exploded. At the time, U-DETA fuel was used in small storable missiles like the Bullpup.

At 0825 hours on 16 June 1955, the submarine *HMS Sidon*, a submarine of the S class, was lying alongside the depot ship *HMS Maidstone* at Portland, UK, when one of her torpedoes exploded [953]. The torpedoes had no warheads but contained hydrogen peroxide propellant. A peroxide line ruptured due to a system overpressure, and this allowed the peroxide to contact incompatible materials like copper and mild steel (a similar failure is thought to be the cause of the more recent, tragic loss of the Russian submarine, *Kursk*). The crew had just embarked the torpedoes before going to sea for trial firings. A sudden uprush of air and smoke poured through the conning tower hatch. The captain, other people on the bridge, and crew from *HMS Maidstone*, entered the boat to assist with the rescue operations. At 0845 hours, the submarine sank without warning. There were 56 men onboard at the time. Three officers and ten ratings lost their lives, but the remainder were saved. The wreck was raised on 23 June 1955 and beached the next day. The 13 bodies were recovered 2 days later. Another explosion of the hydrogen-peroxide torpedo at Arrochar torpedo range caused the development of the Mk12 torpedo to be canceled.

In Japan in 1999, a tanker truck loaded with 500 L of hydrogen peroxide waste blew up on the Tokyo Expressway [426]. The explosion was so strong that it blew off a 10-m section of a 2-m high soundproof barrier, scattering chunks of the wall onto cars

and passersby on the street 8.5 m below. Shockwaves from the blast shattered several windows of 28 buildings in the area. Fragments of the tank were scattered over a 100 m radius.

Table 62 is a summary of hydrogen peroxide transportation accidents, covering only a short period of several years.

Table 62: Accidents caused by H_2O_2 in USA and New Zealand – 2-year sample.

Date	Location	Fatalities	Injuries	Remarks
01/27/2005	San Bernardino, California	N/A	0	Tank container
01/13/2005	Vacaville, California	N/A	0	Road tanker

04/24/2004	Dallas, Texas	N/A	N/A	Tank container
04/05/2004	Mobile, Alabama	N/A	N/A	Waste storage
02/17/2004	Nr. Natchez, Mississippi	N/A	N/A	Transport

Data source: [954]

In 2000, an explosion injured 16 people in Stratford, CT, USA; this accident cost US \$700000.

Butadiene-free radical polymerization with hydrogen peroxide in the presence of an organic solvent occurs in the liquid phase at about 393 K (120 °C). Because of the reactive compounds involved and the relatively high temperature, this is an intrinsically dangerous reaction [955]. The presence of carboxylic acids and/or ionic iron contamination must be avoided.

The company named Peroxide Propulsion in Gunnilse, Sweden, was a producer of rocket grade hydrogen peroxide (also called HTP, high test peroxide) from 2004 to 2010. Lower grade hydrogen peroxide was concentrated to 80–90% concentration in a plant and treated in special processes to produce a very pure product well suited for gas generation and rocket propulsion. Some rocket projects in the US purchased peroxide supplies from the Swedish firm. On July 22, 2010 Peroxide Propulsion suffered a terrible accident at the production facilities in Gunnilse, Sweden. Founder and coowner, Erik Bengtsson, was working at the plant when hot hydrogen peroxide steam exploded in his face, blinding him temporarily. The plant subsequently burned to the ground. All stored supply of propellant-grade hydrogen peroxide was destroyed in the fire, and the company ceased operations [956].

On September 15, 2010, a powerful explosion occurred on the 307 National Highway in Jinzhou, Hebei, China [457]. The explosion was caused by a truck loaded with 5 tons of hydrogen peroxide. Shockwaves from the blast shattered most windows in a 150-m radius. Fortunately, there were no fatalities, but 19 people had injuries from flying debris.

Factory Mutual Insurance Co. has publications that summarize loss histories of hydrogen peroxide accidents in the industry [957, 958]. It does not include accidents at government installations.

One accident was caused by sudden decomposition of hydrogen peroxide in a caustic solution used in a chemical oxygen-iodine laser (COIL) test facility. An outdoor metal tank containing up to 300 gallons of high-concentration hydrogen peroxide exploded at a laser-testing facility at TRW in California, and the event was reported in 1999 [400, 401]. No one was hurt. The hydrogen peroxide in the tank had begun to decompose rapidly, generating enough pressure to blow the tank into three pieces of shrapnel. The tank had a pressure-relief system, but it was not adequately sized to handle the high gas release rates that occurred. It was believed that the tank had accumulated basic hydrogen peroxide (BHP) over a period of 3 months of laser testing during which the BHP was returned to the tank after testing and recycled for additional testing. The BHP was a hydrogen peroxide solution containing potassium hydroxide, lithium hydroxide, and sodium hydroxide. The preliminary finding was that overpressure in the tank was caused by the rapid decomposition of the hydrogen peroxide due to long-term storage, reuse, and consequent contamination of the hydrogen peroxide in the tank.

At NASA Stennis, a rapid decomposition event accident happened during a test of a catalyst bed assembly using H_2O_2 , at approximately 1 s into the test [439, 959, 960]. The test article and facility were damaged, but there were no injuries sustained by personnel. The event occurred approximately 1 s into the test following the completion of a successful test. Damage to the facility included rupturing a 1-in. (2.54 cm) diameter stainless steel supply line rated for 29 MPa (4200 psi) and the destruction of a pre valve rated for 20.7 MPa (3000 psi) service. For the test article, 14 1.27-cm (0.5-in.) diameter stainless steel bolts failed in tension, and a portion of the test article (7.3 kg = 16 lb_m) was ejected 30 m from the test stand. Subsequently, an investigation was conducted, and the causes of the incident were determined. There were several tests run on the night of the incident. Between the second to last test and the test in which the incident occurred, a leaking shutoff valve allowed liquid H_2O_2 to accumulate in a hot supply line just upstream of the catalyst bed. The temperature in this supply line region was approximately 394 K (250 °F). Liquid in the 373 to 422 K (212 to 300 °F) temperature range will create an ignitable vapor for 98% H_2O_2 . When the accumulated vapor was compressed by the opening of the valve for the last test, a rapid decomposition occurred.

A summary of accidents caused by HTP was compiled by staff at NASA WSTF [401]. It was hoped that understanding the causes and effects of these accident and incident examples would aid personnel currently working with HTP to mitigate and avoid similar situations. Lessons learned, best practices, and regulatory compliance information related to the cited accidents and incidents were also discussed.

Putting colloidal silica and sodium silicate into a tank with hydrogen peroxide resulted in an explosion, and it was fortunate that nobody got wounded or killed [961].

Within a period of 15 years, at least 3 bleach plants in North America experienced catastrophic equipment failures associated with the use of 50 mass-% hydrogen peroxide as a bleaching agent for paper and pulp, and people were badly injured in two instances [962].

7.8 Accident Histories of Hydrogen Peroxide Spills

When a semitrailer truck overturned near Romulus, MI on 14 July 2010, 300 gallons of hydrogen peroxide spilled onto the I-275 freeway [963]. The accident happened during the morning commute, and the freeway remained closed at I-94. The big concern was that a chemical reaction could happen and that there would be a sudden explosion. Nearly two miles of I-275 North just south of I-94 were shut down.

About two-thirds (about 22000 gallons) of the contents of a rail tank car loaded with 70% H_2O_2 spilled and leaked into a nearby ditch over 2 h when a slowly moving rail tank car was punctured by a log stacker forklift in a sawmill log yard next to a paper mill in Longview, WA [964]. Fire department crews sprayed water on the spill to dilute the hydrogen peroxide and fortunately nothing ignited when it came into contact with the oxidizer.

The following three transportation (one rail and two air transportation) incidents were quoted by [401]:

An aircraft transportation incident involving hydrogen peroxide occurred in 1988, and a passenger aircraft had to make an emergency landing after smoke, odor, and a softening of the cabin floor was detected. 120 passengers, 4 flight attendants, and 2 flight crew members followed emergency evacuation procedures. Nine passengers, two firefighters and three airline employees suffered minor injuries. The total repair costs for the airplane were \$228823. In this incident, 5 gal of undeclared and improperly packaged 50% H_2O_2 was transported in a fiberboard drum that also contained a 35% H_2O_2 container and a sodium orthosilicate-based material (laundry detergent). The drum was not affixed with directional arrows and had been stowed on its side. The 50% H_2O_2 was packaged in a 5-gallon, non-vented DOT-34 polyethylene drum. The investigation concluded that the 50% H_2O_2 leaked, coming into contact with the fiberboard, resulting in a fire.

Another aircraft transportation incident involving hydrogen peroxide occurred on 28 October, 1998 (National Transportation Safety Board No. DCA-99-MZ-001). Two gallons of a 35% H_2O_2 solution spilled in the cargo compartment of a passenger airplane flying from Orlando, FL to Memphis, TN. The solution leaked from two undeclared 1-gallon plastic bottles. The bottles were in an ice chest that belonged to a passenger on the flight and had not been properly checked as baggage. The leaking hydrogen peroxide contaminated three mail sacks and an undetermined number of passenger baggage pieces. The leak was not discovered until cargo handlers in Memphis began to unload the baggage. Thinking that the spilled liquid was water, the cargo handlers

ignored it and transferred some of the baggage to another passenger-carrying flight departing for Seattle, WA. When the flight arrived in Seattle, two bags in a cargo compartment were smoldering. One handler said the smoke was “like someone blowing on a good cigar.” As a result of the spill, several people required treatment. In Memphis, 11 employees were treated at the airport’s first aid station because their hands (which were tingling and turning white) had been exposed to the hydrogen peroxide. In Seattle, the employee who removed the smoldering bags from the cargo compartment was exposed to fumes and went to hospital for treatment.

A runaway train in Helena, Montana, collided with a helper train and derailed in 1989. Approximately 26250 gallons of 70% H_2O_2 in two tank cars, and approximately 12136 gallons of isopropyl alcohol from another tank car were released. A fire and explosions resulted. About 3500 residents of Helena, Montana had to be evacuated. Two crewmembers were slightly injured. The NTSB believed the H_2O_2 in contact with contaminants on the ground caused a chemical reaction that resulted in a fire. Seven individuals were treated for minor injuries associated with smoke inhalation, headaches, dizziness, sore throats, lacerations, anxiety, and fainting. The estimated damage (including cleanup and lading) exceeded 6 M\$. In this report, the NTSB briefly discussed a previous hydrogen peroxide release in which spilled hydrogen peroxide ignited several wooden rail crossties.

A richly illustrated personal account of H_2O_2 incidents at NASA Langley, based on stories provided by a former NASA employee and either oral history or personal knowledge, was posted on the internet [965]. It described that in the early 1960s, many of the supersonic fighter models tested in the supersonic wind tunnel at NASA Langley had hydrogen peroxide-powered thrusters to simulate the exhaust from an air-breathing jet engine. The exhaust from a turbojet engine could be closely simulated (temperature, gamma, initial plume angle, etc.). Although the exhaust simulation was not as good, a gradual change to cold high-pressure air exhaust simulation was made in the late 1960s because of increasing cost of H_2O_2 , which was used at a prodigious rate. The historic illustrations show how HTP was brought into the facility in railroad tank cars, stored in two above-ground storage tanks, and transferred to truck-mounted fueling carts. Also shown are the catastrophic results of a fire that erupted in a wind tunnel model of a F-11F-1 fighter model after a H_2O_2 leak. Also shown are the remains of the pants of a worker that caught on fire after he accidentally stepped into or knocked over a bucket with HTP. Many of the silver catalyst packs in the models had deteriorated and lost their activity before the test was completed and were spewing undecomposed wet H_2O_2 out in the vicinity of the test cell. Another incident occurred when an HTP monopropellant rocket that was to simulate the Apollo Command Module escape rocket separating from the command module was tested prior to installation in the wind tunnel and burst open, spilling the entire load of the run tank into a trench, and the overflow from the trench ignited the ground surrounding the building.

A table in a fire and explosion hazards of liquid propellants and related materials report lists the number of reported incidents with liquid rocket propellants. Hydrogen peroxide had the highest number of reported incidents of all propellants on that table.

Appendix E of the *HTP Manual* prepared by NASA WSTF contains a 22-page account of numerous hydrogen peroxide accidents, close calls, and lessons learned [966].

8 Toxic Properties of Hydrogen Peroxide

Dilute solutions of hydrogen peroxide are non-toxic since it is an intermediate in many metabolic processes, such as the conversion of sugars and proteins into carbon dioxide and water, allowing many living organisms to function and allowing us to move muscles and perform work. In short, if we did not have H_2O_2 in our bodies, we could not live. H_2O_2 is produced during normal aerobic cell metabolism. Using a radio-isotope technique, an average plasma level of $34\text{ }\mu\text{mol/L}$ (range $13\text{--}57\text{ }\mu\text{mol/L}$) H_2O_2 was found in human volunteers. The average blood level was $288\text{ }\mu\text{mol/L}$ (range $114\text{--}577\text{ }\mu\text{mol/L}$), suggesting that red or white blood cells are rich in H_2O_2 . It involves several enzymatic reactions, especially superoxide dismutase. H_2O_2 is decomposed to oxygen and water by enzymes such as catalase, peroxidase, and selenium-dependent glutathione peroxidase. Nevertheless, there is concern about the role that free radicals, such as the hydroxyl radical, which is formed as an intermediate during hydrogen peroxide decomposition, play in the aging of living cells and triggering of cancer. Many health stores advertise “radical scavenger” food supplements. The most readily available food supplement in this category and a good reducing agent is ascorbic acid (Vitamin C). At the same time, we must remember that hydrogen peroxide in higher concentrations is used as a disinfectant and as a mouthwash and will kill many small microbes.

Several good summaries of HTP toxicity, also in comparison with other propellants, have been published [967], but they need to be updated from time to time. The most comprehensive evaluation of hydrogen peroxide toxicity was compiled by the European Centre for Ecotoxicology and Toxicology of Chemicals as part of their Joint Assessment of Commodity Chemicals in 1993 [968]. The paper by Jacobi has a very good list of references on toxicity of hydrogen peroxide [969].

8.1 Inhalation Toxicity of Hydrogen Peroxide

The vapor pressure of hydrogen peroxide at room temperature is so low that the vapors evolving from hydrogen peroxide during open transfer do not constitute an acute inhalation toxicity hazard if adequate ventilation is provided (i.e., you stay upwind of it).

Figure 68 in the *Encyclopedia of Liquid Fuels*, chapter “Hydrazine”, gives a comparison of the hazard indices of various storable propellants. The hazard index is the quotient of vapor pressure divided by the LC_{50} or the Threshold Limit Value (TLV) concentration. The lower the threshold toxicity concentration, the higher the hazard index.

Aerosols can form if hydrogen peroxide sprays from a leak under high pressure. Hydrogen peroxide aerosols can be quite irritating to the mucous membranes and respiratory tract. Decomposition products of hydrogen peroxide that is actively decomposing in an open container will carry with them a certain amount of undecomposed H_2O_2 , which constitutes an irritant and respiratory hazard. Inhaling H_2O_2 aerosols at the scene of a leak causes significant immediate irritation of the respiratory tract and gasping, like that encountered when accidentally walking into a cloud of ammonia gas. A sharp, burning sensation in the nasal passages should warn workers to seek fresh air as fast as possible. Respiratory irritation in humans for repeated 4-h exposures starts at 10 mg/m^3 , and irritation of the skin starts at 20 mg/m^3 .

In the 1950s, it was the general attitude that the inhalation of vapors resulting from the spillage of 90% H_2O_2 do not constitute a major respiratory hazard [970, 971].

Acute exposure of mice to H_2O_2 vapor concentrations of 9400 mg/m^3 was rapidly fatal for most of the animals in the cage. Repeated exposure of mice to 80 mg/m^3 was still fatal to some of the animals.

In examining the categorization of HTP as a “non-toxic propellant” more closely, the reader will soon realize that in the more critical workplace toxicity hazard evaluation of the 1990s this statement can no longer be accepted, and more restrictive protective measures are now being taken.

8.2 Inhalation Toxicity Test Results

The following is a summary of animal tests that were conducted to determine the safe threshold for human exposure to HTP vapors. Some of the early investigators failed to report if the chemical was administered in the form of vapors or aerosols.

8.3 Chronic Inhalation Toxicity – Animal Tests

Because H_2O_2 decomposes so quickly on surfaces, it is difficult to maintain constant H_2O_2 vapor concentrations in the animal exposure cages for long periods of time.

Groups of rats were exposed to nominal “saturated” 4000 mg/m^3 (2840 ppm by volume) H_2O_2 vapors for 1 to 8 h but all animals survived with only minor clinical signs. Three groups of 10 male Wistar rats were exposed to 338 to 427 mg/m^3 (243 to 307 ppm by volume) H_2O_2 vapors for 4 h/day for up to 2 weeks [972]. Initially, they did not show any signs of poisoning, and all survived the experiments, but after 4 to 14 days of expo-

sure, some were sacrificed and necropsied, and it was noted that several had suffered lung edema and showed areas of alveolar emphysema. Other groups of rats were exposed to subacute concentrations ($79 \text{ mg/m}^3 = 57 \text{ ppm}$ by volume) for 6 h daily, 5 days/week for 6 months. All animals suffered irritation of the respiratory tract, and the hair of their fur was bleached. Brief exposure to aerosols at $9400 \text{ mg/m}^3 \text{ H}_2\text{O}_2$ was lethal to mice with effects limited to the respiratory tract and the eyes. After repeated exposure, mortality in mice was observed starting at 80 mg/m^3 . In rats and dogs, respiratory irritation and transient skin thickening have been observed at $1\text{--}10 \text{ mg/m}^3$ after prolonged exposure.

Dogs were exposed to $10 \text{ mg/m}^3 = 7 \text{ ppm H}_2\text{O}_2$ for 6 h/days, 5 days/week for 6 months. All animals suffered chronic irritation of mucous membranes, leading to sneezing and weeping. Again, their fur was bleached. After completion of the test, selected tissue samples were examined, and most lung tissues showed pathologic changes. Based on these tests, it was suggested that 4 ppm would be a safe concentration for workers, but that would not include any margin for safety. The ACGIH-recommended TLV for H_2O_2 as an 8-h time weighted average (TWA) is 0.14 mg/m^3 or 0.1 ppm [973].

A study of the short-term toxic effects in mice exposed to aerosols formed from 90% H_2O_2 in air showed that beginning mortality occurs at 13 mg/L for 10 min [974]. At concentrations from 3.6 to 5.2 mg/L no fatalities were observed for 5-min exposures. At 9 mg/L the threshold of fatality was reached, where some delayed fatalities occurred only 6 days after the end of the exposure. A 15-minute exposure to 12 to 19 mg/L can be fatal within 1 h (Table 63). Exposure to concentrations of up to 5 mg/L (3535 ppm) for 5 min produced evidence of mild nasal irritation, blinking, and slight gasping. There were no deaths from 5 mg/L exposures, but there was evidence of lung congestion at necropsy. Four out of twenty mice exposed to 5.2 mg/L (3676 ppm) showed necrosis of the bronchial epithelium. Animals exposed to concentrations of 9.4 mg/L

Table 63: Toxicity of 90% H_2O_2 aerosol in mice.

Inhalation duration Min	H_2O_2 concentration mg/L in air	Mortality	Survival time Min
5	3.6	0/10	
5	4.2	0/10	
5	5.2	0/10	
5	5.2	0/10	
5	9.4	0/10	
10	13.2	5/10	12 min to 6 days
10	13.4	1/10	6
10	19.0	1/10	11
15	11.8	5/10	5–50
15	16.7	9/10	11–50

Data source: [974]

(6645 ppm) or more for 5–15 min showed similar but more severe signs, and 10–50% of animals died within 1 h following a short convulsing period. Most of the animals that died showed pulmonary congestion. Animals that survived for several days to 8 weeks showed necrosis of the bronchial epithelium. In addition, animals surviving 9.4 mg/L (6645 ppm) or more suffered slowly developing corneal damage, which appeared about 5 weeks after exposure.

Whole-body exposure of white rats for 4 h to various concentrations of H_2O_2 , vaporized from a solution, resulted in an LC_{50} of 2000 mg/m^3 . The LOEC for the respiratory mucosa was 60 mg/m^3 , and exposure at 110 mg/m^3 produced hyperanaemia and transient thickening of the skin [975].

Inhalation Toxicity – Human Volunteer Tests

Hydrogen peroxide aerosol or vapor causes irritation and in severe cases damage to the upper respiratory tract and lungs [976]. The human response to the irritating effect of hydrogen peroxide on the mucous membrane and skin is far more sensitive than that of the rat. The threshold concentration for acute irritative effects of gaseous hydrogen peroxide on the respiratory tract is 60 mg/m^3 in rats, but only 10 mg/m^3 in humans; the corresponding values for skin are 110 mg/m^3 for rats and 20 mg/m^3 for humans.

In a study conducted in 1976, human volunteers were exposed to hydrogen peroxide vapors for different periods of time [975]. Respiratory irritation was assessed by nasal inhalation of H_2O_2 vapor. It was noted that irritation depended upon exposure concentration and to a lesser extent on exposure duration (between 5 min and 4 h). The threshold for respiratory irritations was found to be 10 mg/m^3 (7 ppm) in all cases. A statement by certain HTP-promoting marketing-type speakers [977] like: “There is growing evidence that HP does not lead to **any** systematic toxic effects” is irresponsible and totally wrong.

Eleven healthy volunteers were exposed to 0 (clean air), 0.5 and 2.2 ppm H_2O_2 for 2 h at rest to investigate subtle acute effects of inhaled hydrogen peroxide vapors [978]. Symptoms related to irritation and central nervous system effects were rated with visual analog scales. The ratings varied considerably but were generally low and with no significant differences between exposure conditions, although the ratings of smell ($p = 0.09$, Friedman’s test), nasal irritation ($p = 0.06$), and throat irritation ($p = 0.06$) showed borderline tendencies to increase at 2.2 but not at 0 and 0.5 ppm. Nasal airway resistance increased after exposure to 2.2 ppm hydrogen peroxide ($p = 0.04$, paired t-test) but not after 0.5 ppm. No exposure-related effects on pulmonary function, nasal swelling, breathing frequency, and blinking frequency were detected. No clear effects were seen on markers of inflammation and coagulation (interleukin-6, C-reactive protein, serum amyloid A, fibrinogen, factor VIII, von Willebrand factor, and Clara cell protein in plasma). In conclusion, the study suggested that hydrogen peroxide is slightly irritating at 2.2 ppm but not at 0.5 ppm.

It was claimed that “Humans are regularly exposed to greater than 1 ppm in some common foods and human breath can exceed 1 ppm from the natural hydrogen peroxide produced inside humans” [840], but we have been unable to verify this assertion. It was argued that if exhaled human air can contain more than 1 ppm H_2O_2 , then the 8-h TLV-TWA at the workplace established by ACGIH should be higher than 1 ppm.

8.4 Skin Effects of Hydrogen Peroxide

The hydrogen peroxide that permeates into skin quickly reacts with body fluids containing blood, glutathione, and enzymes and decomposes into water and oxygen. The decomposed hydrogen peroxide forms tiny gas bubbles on the skin surface capillaries creating microembolisms, which locally block blood flow in the skin causing a lack of blood flow and a change in the skin color from its natural flesh tone to white (Figure 58). Once the oxygen bubbles are absorbed into the body, blood flow returns to the skin, and the color returns to normal.

Figure 58: Effect of skin exposure to 35% hydrogen peroxide. (From https://en.wikipedia.org/wiki/Hydrogen_peroxide. Posted by Olli Niemitalo into the public domain on 13 April 2010)

Application of 90% H_2O_2 to the shaved skin of rabbits caused H_2O_2 absorption through the skin and caused death by gas embolism [979]. The dermal LD50 is 690 mg/kg for 90% HTP in the rabbit [980]. Additional fatality data were obtained on cohorts of pigs, dogs, and white and dark rats with doses from 2700 to 8200 mg/kg but insufficient data points to bracket an LD50.

The dermal toxicity of solutions of 35–75% H_2O_2 in rabbits was low (LD50, dermal, rabbit: >2000 mg/kg). LD50 values of 90% H_2O_2 ranged from ca. 690 mg/kg in rabbits to >2000 mg/kg in rats, pigs, and cats.

Skin contact with solutions containing more than 25% H_2O_2 is dangerous and damaging. On the thick skin on the inside of the hands, one quickly develops white and bleached spots and an itching sensation that abates after a few hours. The bleached spots persist for several days. It is believed that the white appearance and

opacity is formed by thousands of tiny gas bubbles formed in the thicker sections of skin by local decomposition of H_2O_2 as it permeates the skin. They do not last as long as the persistent yellow stains on the hands of negligent rocket test site or laboratory workers who have accidentally contacted nitric acid. HTP that has wicked under the fingernails is extremely painful. Higher concentrations of H_2O_2 can cause severe blistering if the liquid is not immediately washed away with large amounts of water. HTP causes immediate irritation in skin sections other than the hands where the keratin is thinner. The recommended first aid treatment for inadvertent H_2O_2 skin exposure is flushing with large amounts of water. For additional information, consult the Material Safety Data Sheets (MSDS) available from HTP suppliers.

Contact of hydrogen peroxide with the skin can cause severe skin damage. An accident report describes a case of skin injury induced by 35% hydrogen peroxide [981]. The patient was a 34-year-old man working in a dry-cleaning shop. While he was pouring 35% hydrogen peroxide, some of it accidentally splashed over his left shoulder and back. Soon after the exposure, an erythema, purpura, and vacuolar eruption, similar to bubble wrap, appeared on his left shoulder and down the left side of his back. Histologically, numerous vacuolar structured “oxygen bubbles” were observed in the epidermis, dermis, and subcutaneous tissue. Subcutaneous emphysema was detected by chest X-ray examination. All skin eruptions healed without scarring, and the healing was helped by the use of a steroid ointment.

Acute dermal toxicity depends on hydrogen peroxide concentration. With 90 mass-% hydrogen peroxide, the dermal LD50 in rabbit is 650 mg/kg, and in rat it is 4800 mg/kg [982].

8.5 Eye (Ocular) Effects of Hydrogen Peroxide

Besides pulmonary damage with frequently deadly consequences, high concentrations of H_2O_2 vapors may also cause opacification of the cornea. Splashes of liquid H_2O_2 into the eye cause turbidness of the cornea and can cause permanent blindness. Even H_2O_2 vapors can cause eye irritation, but usually without permanent damage, if the person is removed from the source of the vapors quickly, and the eyes are flushed with water at the eye wash fountain.

H_2O_2 solutions of 10% or more cause irreversible damage to the eye, including blindness. Solutions of less than 5% are not classified as irritant to the rabbit eye. The first effects on the rabbit cornea were observed with a 1% solution. In human beings, 1–3% solutions have been used for eye treatment without significant injury.

In animal tests, the ocular irritancy of 5–70% H_2O_2 solutions has been evaluated in rabbits: 0.1 mL was instilled into the conjunctival sac, and in certain cases, the eyes were washed with 100 mL tap water after 20–30 s [983]. A 5% solution caused minimal irritation to unwashed eyes. An 8% solution was moderately irritating to unwashed eyes (exhibiting severe conjunctivitis, slight corneal opacities, and iritis). A 10% so-

lution was extremely irritating to both washed and unwashed eyes: severe corneal opacity, iritis, and conjunctivitis were the result. A 35% solution was extremely irritating, producing corneal opacities, iritis, and moderate conjunctivitis, blanching of the conjunctiva, haemorrhagic iris, bubbles under the cornea, blanching of the cornea, or corneal ulcerations. A 70% solution was extremely irritating and corrosive to the eyes of rabbits.

8.6 Oral Toxicity of Hydrogen Peroxide (Animal Tests)

8.6.1 Animal Tests

Accidental oral (PO) ingestion of hydrogen peroxide is said to include the danger of rupturing of internal organs due to excessive gas evolution and overpressurization. Predominant clinical signs in rats administered 35% H_2O_2 included tremors, decreased mobility, prostration and oral, ocular, and nasal discharge. Most animals that died had reddened lungs, hemorrhagic and white stomachs, and blood-filled intestines. Some had white tongues. Table 64 is a summary of oral toxicity tests with different concentrations of hydrogen peroxide in rats.

Table 64: Oral toxicity of hydrogen peroxide solutions in rats.

Concentration of solution Mass-%	Strain	Sex	LD50 mg/kg	Observation period d	References
9.6	Wistar-JCL	Male	1517	7	[984]
9.6	Wistar-JCL	Female	1617	7	[984]
